## Light-sensitive membrane potentials in onion guard cells

INTRACELLULAR electrical recordings in onion guard cells show that they maintain a membrane potential difference (MPD), inside negative. The MPD is light-sensitive; cells subjected to short light and dark cycles depolarise in the dark and hyperpolarise in the light. The swiftness of the electrical changes makes them among the fastest known stomatal responses, suggesting a causal relationship between the reception of light, the changes in membrane potential and the ion fluxes known to be associated with stomatal movement. The magnitude and electrical sign of the responses are consistent with the activity of a light-sensitive proton pump which would provide the driving force for ion transport across the cell membrane. Guard cells, the specialised structures that control gas exchange in the leaves of higher plants, use potassium to modulate their intracellular osmotic potential and perform the mechanical work needed to open and close the stomatal pore<sup>1</sup>. When guard cells accumulate K<sup>+</sup> (with intracellular concentrations reaching up to 0.5 M (refs 2 and 3)), water content increases and swelling occurs, causing the pore to open. During the reverse process, K<sup>+</sup> is extruded (intracellular concentration diminishes to 0.1 M (refs 2 and 3)), leading to water loss and pore closure. Control of intracellular K<sup>+</sup> concentrations is a universal feature of living organisms. Nerve cells store energy used to generate electrical signals by maintaining concentration gradients of Na<sup>+</sup> and K<sup>+</sup> (ref. 4); bacterial cells selectively accumulate K<sup>+</sup> (ref. 5) and, in plants, cells expand by increasing their turgor through uptake of K<sup>+</sup> and its counter-ions<sup>6</sup>. While the cellular basis of K<sup>+</sup> uptake in stomatal guard cells is poorly understood, one might expect common mechanisms for K<sup>+</sup> transport even in widely divergent species. Two distinct mechanisms for K<sup>+</sup> transport have been defined. In one, common in animal cells, K<sup>+</sup> uptake is driven by ATP through a Na<sup>+</sup>/K<sup>+</sup> ATPase<sup>7</sup>; in the second system, demonstrated in bacteria, ion transport is conducted by a proton-motive force<sup>8</sup> generated by pH and electrical potential gradients across the membrane<sup>9</sup>. In showing that wall-less guard cell protoplasts swell when illuminated, we previously argued that a proton-motive force could drive K<sup>+</sup> uptake into the guard cells<sup>10</sup>. The hypothesis generates the basic prediction of a light-sensitive, inside negative, MPD across the guard cell membrane. We report here the experimental verification of that prediction, through intracellular recordings in guard cells of *Allium cepa*.

Both intact guard cells and cells with walls partially digested with a cellulolytic enzyme were used. Partial digestion of cells facilitated electrode penetration and gave us a basis for work on MPD and cell compartments, which are discussed elsewhere<sup>11</sup>. Slices from cotyledons of 7–14 d-old seedlings were the tissue source for both types of preparations<sup>12</sup>. The slices were adhered with a Valap mixture<sup>12</sup> to the bottom of a 5 ml well made in a 9.5-cm Petri dish filled with Sylgard (Dow Corning) and bathed with a 0.23 M mannitol solution containing 1 mM KCl and 1 mM CaCl<sub>2</sub>. The wall digestion was made with a 2% (w/v) solution of Cellulysin (Calbiochem) in the above solution for 2–5 h. At the end of the digestion, the preparation was washed twice with enzyme-free, bathing solution. Both types of preparations were dark adapted for 1–4 h before the experiments. Guard cells were impaled with glass capillary microelectrodes under direct visualisation at 400× magnification using a Zeiss compound microscope with a water-immersion objective. Microelectrodes were filled with 3 M KCl and bevelled after filling to final resistances of 40–90 MΩ. The signal from the microelectrode was put

through a high input impedance preamplifier and displayed on a cathode-ray oscilloscope and a slow speed chart recorder.

All guard cells showed MPD, inside negative. Partially digested cells averaged  $-39 \pm 7$  mV ( $n=65$ ) and intact guard cells  $-72 \pm 29$  mV ( $n=40$ ). Exposure of the cells to light cycles showed that the MPD is light-sensitive. Guard cells were impaled under dim green light, and those showing steady MPD ( $\pm 2$  mV) for at least 5 min, were subjected to alternating short dark and white light ( $200\text{--}500 \mu\text{E m}^{-2} \text{s}^{-1}$ ) cycles. The cells typically depolarised in the dark and hyperpolarised in the light (Fig. 1). Both intact and partially digested cells exhibited the electrical changes but the former had faster and larger responses. Depolarisations ranged between 1 and 60 mV; hyperpolarisations between 1 and 52 mV. The initial stages of the responses showed the highest rates, reaching as much as  $1.7 \text{ mV s}^{-1}$  for the depolarisations and  $0.9 \text{ mV s}^{-1}$  for the hyperpolarisations. Initial rates varied greatly, though, averaging about  $14 \text{ mV min}^{-1}$  for depolarisations and  $8 \text{ mV min}^{-1}$  for hyperpolarisations. After an initial fast phase, the responses become slower, saturating with approximately exponential kinetics (Fig. 1b). In addition, prolonged depolarisations showed a second, slow phase (Fig. 1b) which could not be observed in the hyperpolarisations. Actively responding cells showed alternating responses throughout 3–5 consecutive light/dark cycles with latencies ranging from 1–45 s (Fig. 1a). Typically, the depolarisations had shorter latencies.

It seems likely that these electrical responses of the guard cells are normal physiological events, associated with the K<sup>+</sup> fluxes seen during stomatal opening and closing. The short latencies and high initial rates of these light-induced membrane potential changes suggest that they could be an early and primary event in the mechanism controlling stomatal movement. The fact that the latencies of the dark responses, which we interpret as related to stomatal closing, are of the same order of magnitude as the latencies reported for closing in response to high CO<sub>2</sub> concentrations<sup>13</sup> also suggest a primary effect of light. The present results argue against the possibility that stomatal light responses are indirect and CO<sub>2</sub>-mediated<sup>14</sup>, since it is difficult to envisage that dark would cause a CO<sub>2</sub>-mediated response with the same latency as the CO<sub>2</sub> response alone. The data suggest, instead, that both dark and CO<sub>2</sub> can elicit a primary response leading to closing. Our observations showing that isolated guard cells from digested preparations also exhibit light-sensitive MPD indicate that light energy was absorbed by photopigments within the guard cell, without the mediation of other cells of the tissue.

An electrogenic mechanism driving K<sup>+</sup> transport in the guard cells has been suggested before<sup>1</sup> but the hypothesis has not become widely accepted because of negative reports on MPD across the guard-cell membrane<sup>2</sup> or its sensitivity to light<sup>15</sup>. The data presented here and related observations by Gunar *et al.*<sup>16</sup> give new support to the notion of an electrogenic pump being the driving mechanism of stomatal movement.

Light-induced electrical events associated with pump activity are well known in other systems. Vertebrate photoreceptors hyperpolarise when illuminated due to a change in membrane Na<sup>+</sup> conductance, probably mediated by the release of Ca<sup>2+</sup> from intracellular stores<sup>17</sup>. It is of interest that both onion guard-cell protoplasts<sup>10</sup> and outer-rod segments isolated from frog retinae<sup>18</sup> change their intracellular osmotic potentials in response to light. It seems plausible that the two cell types might share common mechanisms underlying phototransduction and ion fluxes.

Another useful system which provides insight on the basis of light-driven energy transduction coupled to ion transport has been described in *Halobacterium halobium*. In

**Fig. 1** Intracellular electrical recording in onion guard cells showing the changes in membrane potential differences in response to light and dark cycles. *a*, Three alternating dark/light cycles in an intact cell. Shaded portions in the abscissa show the dark periods, arrows point to the onset of each alternating stimulus. *b*, Dark and light response in a partially digested cell, seen at a higher gain. Both depolarisations and hyperpolarisations saturate with apparent exponential kinetics, with the depolarisations showing a second slower phase.

this microorganism a membrane-bound photopigment, bacteriorhodopsin, extrudes protons when illuminated, thus generating an electrochemical gradient across the cell membrane. This proton motive force can then be used to drive passive  $K^+$  influx<sup>19</sup> or to make ATP (ref. 20). In addition, ATP hydrolysis can be used to poise the proton gradient independently of illumination<sup>20</sup>, thus making the gradient a central device for the transduction of energy from either light or respiration<sup>21</sup>. Light-induced membrane hyperpolarisations ranging between 24–67 mV have been measured in *Halobacterium*<sup>22</sup>.

The demonstrated ability of a proton gradient to drive  $K^+$  uptake in the light and in the dark makes it a possible mechanism for energising ion transport during stomatal movement. Most of the known physiological properties of the guard cells seem consistent with the hypothesis and our findings of a light-sensitive MPD in onion guard cells adds new, though indirect, evidence.

The demonstration of a proton gradient across the guard-cell membrane as a primary energy-transducing mechanism would provide a link between the several possible energy sources used by the guard cells to drive ion fluxes. Blue light energy could be directly transduced as an electron flow when absorbed by a photoreceptor (a flavin?) which would be one of the links in the membrane-bound, electron transport chain which generates the

gradient. In addition, ATP hydrolysis would constitute a major energy source poising the gradient. ATP could be formed by oxidative phosphorylation in the guard cell mitochondria, which would be light independent and able to drive ion fluxes in the dark or by photophosphorylation in the guard cell chloroplasts which could utilise light energy with the spectral sensitivity of chlorophyll.

## Unprotonated chromophore-protein bond in visual pigments from $^{13}\text{C}$ -NMR spectra

THE chromophore of visual pigments is generally assumed to be a protonated Schiff base of the 11-*cis* retinylidene (rhodopsins) or the 11-*cis* 3-dehydroretinylidene (porphyropsins) groups linked through a lysine amino group to a specific glycolipoprotein moiety (opsin)<sup>1</sup>. This protonated Schiff base hypothesis has been supported by plausible though not unequivocal chemical evidence<sup>2,3</sup>. Recent studies using the physical technique of resonance Raman spectroscopy have also seemed to support this view<sup>4–7</sup>. In an attempt to confirm this assignment and to explore further the structure and microenvironment of the chromophore, we have studied the nuclear magnetic resonance (NMR) spectra of aqueous suspensions of bovine rhodopsin which contain the chromophore enriched with  $^{13}\text{C}$  at specific positions in the retinylidene carbon chain. We report here our findings which clearly support an unprotonated retinylidene Schiff base as the visual chromophore in contrast to the earlier chemical and physical evidence which supports a protonated form.

Retinal isomers were synthesised enriched at the C14 position

from the C18 ketone<sup>8</sup> and triethyl phosphono[2-<sup>13</sup>C]acetate<sup>9</sup>. This latter compound was synthesised from triethylphosphite and ethyl [2-<sup>13</sup>C] bromoacetate. The resulting ester was converted to the [14-<sup>13</sup>C] retinal isomers by LiAlH<sub>4</sub> reduction and MnO<sub>2</sub> oxidation. High pressure liquid chromatography was used to isolate the 11-*cis* isomer of [14-<sup>13</sup>C] retinal<sup>10</sup>. <sup>13</sup>C-labelled rhodopsin was prepared by regenerating freshly photobleached bovine disks with labelled 11-*cis* retinal. After adding hydroxylamine to complex the excess retinal, the rhodopsin was solubilised by adding 50 mM aqueous phosphate-buffered octyl glucoside. Purification and delipidation was accomplished by affinity chromatography on Concanavalin A-Sepharose<sup>11,12</sup> using 30 mM octyl glucoside as detergent. This solution was then concentrated to 1–2 mM and dialysed three times to remove small organic molecules. Nuclear magnetic resonance

(NMR) spectra were collected in the Fourier transform mode on a 14 kG home built (DT) spectrometer as well as a Varian XL-100.

Figure 1a shows the <sup>13</sup>C NMR spectrum of a solution of octyl glucoside-solubilised bovine [14(retinylidene)-<sup>13</sup>C] rhodopsin containing no free retinal isomers. Figure 1b shows a spectrum of a solution of octyl glucoside and unenriched rhodopsin. The spectrum of the enriched pigment contains one additional resonance at approximately 130.8 p.p.m. downfield from TSP-d<sub>4</sub>. This peak is more pronounced in Fig. 2, where the rhodopsin concentration is twice that in Fig. 1a and the <sup>13</sup>C-<sup>1</sup>H dipolar interactions have been removed with high power decoupling. The peak at 175 p.p.m. in Fig. 2 is due to resonances arising from the amide carbonyls of the protein, observed because of the long pulse delay in this experiment.

**Fig. 1a.** <sup>13</sup>C NMR spectrum at 25.16 MHz of a solution of [14 (retinylidene)-<sup>13</sup>C] rhodopsin (0.5 mM) in 0.1 M KH<sub>2</sub>PO<sub>4</sub> buffer (pH 7.0) with 100mM octyl glucoside. Acquisition time, 0.2 s; pulse delay, 0.2 s; 30° pulse angle; 12 mm tube; and 58,170 transients. An external lock was used; **b.** <sup>13</sup>C NMR spectrum at 25.16 MHz of a solution of rhodopsin (0.5mM) in 100 mM octyl glucoside in 0.01 MKH<sub>2</sub>PO<sub>4</sub> buffer with D<sub>2</sub>O added for a lock (pH before D<sub>2</sub>O addition, 7.0). Acquisition time, 0.8 s; pulse angle, 30°; 21 mm tube; 20,000 transients.

Previous work from our laboratory with model visual pigment chromophores, that is, 11-*cis*-retinal, N-11-*cis*-retinylidene-propylimine (NRPI), and N-11-*cis*-retinylidenepropyliminium ion (NRPI-H<sup>+</sup>), have shown that the chemical shift of the C14 position of the protonated Schiff base of retinal is at a significantly higher field (about 120 p.p.m.) than in free retinal and its unprotonated Schiff base (about 130 p.p.m.) (ref. 13 and J.W.S., G.D.M. and E.W.A., unpublished). Quite clearly, there is a large difference in chemical shift of the C14 position between that observed in <sup>13</sup>C-enriched rhodopsin and the model protonated Schiff base of retinal. It is difficult to account for this large difference in terms of microenvironmental interactions. All interactions, steric, coulombic, ring currents, and so on, which are associated with protein folding would generally not lead to chemical shift differences larger than 2 p.p.m.<sup>14-17</sup>.

We have found that salts of model Schiff bases of all-*trans* retinal show the chemical shift of the C14 carbon in a pigment with a visible absorption maximum at 498 nm should be even further upfield than 120 p.p.m. (Fig. 3). In addition, there is a very small variation in the observed chemical shift for model pigments absorbing from 428 to 480 nm in cases where the counterion is associated with the nitrogen atom.

We have calculated the variation of the C14 chemical shift as a function of various counterion placements along the polyene chain from Pariser-Parr-Pople electron densities using the Karplus-Pople formula (ref. 18 and J.W.S. *et al.*, unpublished). These show no anomalous downfield shifts to 130 p.p.m. in a model pigment which has a significant bathochromic shift (about 140 nm) relative to the unprotonated Schiff base. Presumably this is due to the proximity of C14 to the protonation site; a significant negative charge is forced on C14 with protonation, and its magnitude varies little with counterion placement. Therefore, the chemical shift of C14 in a protonated Schiff base chromophore absorbing near 500 nm must be approximately 120 p.p.m. downfield from TMS. Attempting to position a charge such that a chemical shift of 130 p.p.m. would be observed should lead to a long wavelength absorption maximum near 350 nm.

The use of two anionic charges, one placed near the protonated nitrogen atom such as proposed by Honig *et al.*<sup>19</sup> would also be expected to give shifts near 120 p.p.m. downfield from TMS for a pigment with a long wavelength absorption maximum near 500 nm since the C = N region in this case behaves similarly to the solution case. The above considerations clearly argue against the N-protonated retinylidene Schiff base model for the chromophore of rhodopsins.

It is most significant that the C14 shift for rhodopsin is consistent with the chromophore being an unprotonated Schiff

Fig. 2 <sup>13</sup>C NMR spectrum (14 KG field) of a solution of [14 (retinylidene-<sup>13</sup>C) rhodopsin (1.0 mM) in 0.1 M KH<sub>2</sub>PO<sub>4</sub> buffer (pH 7.0) with 100 mM octyl glucoside. Acquisition time, 0.2 s; pulse delay, 2.0 s; pulse angle, 90°; 8 mm tube; and 8092 transients. An external lock was used.

Fig. 3 Variation in shift of C14,  $\delta C14$ , as a function of the long wavelength absorption maximum of all-*trans*-retinylidenepropyliminium ions, a, NRPI-HCl in acetone; b, NRPI-HCl in EtOH; c, NRPI-HCl in CDCl<sub>3</sub>; d, NRPI-HBr in CDCl<sub>3</sub>; e, NRPI plus a 100-fold excess of TEA in CH<sub>2</sub>Cl<sub>2</sub>. ○, Predicted value for a pigment with an all-*trans* chromophore with  $\lambda_{max}$  = 498 nm is 118.26 p.p.m.

base of retinal ( $\delta C14$  = 129.96) or retinal itself ( $\delta C14$  = 129.99 p.p.m.). Chemical evidence indicates that the retinylidene chain is bound to an  $\epsilon$ -amino group of lysine on opsin rather than existing *in situ* as free retinal<sup>20, 21</sup>. This would lend support to the original notion of Dartnall of an unprotonated Schiff base linkage<sup>22</sup>.

The above NMR results run counter to the conclusions drawn from resonance Raman spectra of rhodopsin. The band assigned to  $\nu(C=N)$  of protonated Schiff base linkage by various investigators varies from 1645 to 1660 cm<sup>-1</sup> for rhodopsin having an absorption maximum at 498 nm<sup>13</sup>. Other peaks in the spectra—for example,  $\nu(C=C)$ —vary to a much lesser degree ( $\sim 4$  cm<sup>-1</sup>). Furthermore, bathorhodopsin and isorhodopsin both have a 1665 cm<sup>-1</sup> peak, whereas their visible absorption maxima are 543 and 483 nm, respectively; one would expect to find some variation of  $\nu(C=N)$  with absorption maxima of the chromophore. This line of reasoning, together with the NMR results presented here, suggests that the peak in the 1650 cm<sup>-1</sup> region may be incorrectly assigned.

In conclusion, we point out that the NMR spectra of <sup>13</sup>C-enriched rhodopsin leaves little question of the assignment of the probe signal while in resonance Raman spectra this is not the case. It seems evident from the results reported here that the Dartnall model of an unprotonated Schiff base chromophore in native visual pigments deserves further attention.

KNOWLEDGE of the primary sequences of repressor proteins and the DNA operators with which they interact is essential for detailed study of the molecular aspects of the control of gene expression. The sequences of two repressors are known: the cI protein of lambda (ref. 1 and R. Sauer and R. Anderegg, personal communication) and the *i* gene product of the lactose operon of *Escherichia coli* (refs 2,3 and P. J. Farabaugh, personal communication). Here we report the DNA sequence for the structural gene of a third repressor, the Cro protein of lambda. This protein is of special interest both because of its small size (66 amino acids, as compared with the 236 amino acids of the cI protein and the 360 amino acids of the *lac i* gene), and because genetic evidence suggests that it interacts with the same operator regions as does the cI protein, although the

**Fig. 2** Autoradiogram of a polyacrylamide gel displaying 5' end-labelled oligonucleotide products resulting from partial, base-specific cleavage of the DNA fragment extending to the right of the *Bgl* II site shown in Fig. 1b. To sequence this region of the gene, DNA from a plasmid (A. Johnson, unpublished) containing the portion of the lambda chromosome extending from the rightmost *Hin* III site in the *cl* gene to the *Eco* RI site in the *o* gene was cut with *Bgl* II, dephosphorylated with bacterial alkaline phosphatase, and 5' end-labelled using [ $\gamma$ - $^{32}$ P]ATP and T4 polynucleotide kinase. The resulting labelled fragments were digested with *Hin* II, and separated electrophoretically on a 3.5% polyacrylamide gel. The 440-base pair *Bgl* II-*Hin* II fragment containing the carboxy-portion of the *cro* gene was isolated from the gel and partially sequenced by the chemical procedures of Maxam and Gilbert<sup>8</sup>.

end labelling shown in Fig. 1b. Figure 2 shows an autoradiogram of a typical sequencing gel. The completed DNA sequence is shown in Fig. 3. Wherever possible the DNA sequence was checked by comparison with a catalogue of sequenced oligoribonucleotides generated by both ribonuclease T<sub>1</sub> and pancreatic RNase digestion of the RNA transcript of the region from *P<sub>R</sub>* to *t<sub>RI</sub>* synthesised *in vitro*. All oligoribonucleotides larger than tetramers have been uniquely identified. In this manner independent confirmation was obtained for over 70% of the sequence. The initial 27 bases of the sequence are in agreement with the sequence predicted for the 5' end of *cro* by Steege and Steitz<sup>9</sup> from RNA sequencing of the message initiated at *P<sub>R</sub>*.

Takeda *et al.*<sup>10</sup> have isolated, identified, and determined the protein sequence of the lambda Cro protein. Their amino acid sequence is in exact agreement with that predicted by our DNA sequence. The occurrence of an ochre termination codon immediately beyond the COOH terminal alanine residue indicates that the cellular form of Cro is not processed. Comparison of the amino acid sequence determined for Cro with that of the lambda repressor indicates that no obvious similarities exist in the amino acid sequences of the two proteins.

Several aspects of the *cro* sequence are worth noting. (1) The 5' ATG of our sequence is three bases to the right of the putative ribosome binding site found by Steege and Steitz in the leader of the *cro* message<sup>9</sup> and is 18 bases from the start point of transcription. (2) There is a region of perfect twofold symmetry in the DNA sequence involving bases 130–138 and 145–153. This hyphenated symmetry would give rise to a potential stem and loop structure in the RNA transcript of this region. The significance of this feature is not known; however, it does share the sequence ATAAA . . . . . TTTAT with the right operator region *O<sub>R</sub>*. (3) The region from base 106 to base 125 consists of a G-C rich region (106–113) followed at a short distance by the sequence TTTT TTA (Fig. 2). This primary structure is reminiscent of known sites of *rho* independent transcription termination<sup>11</sup>. But, *in vitro* transcription studies indicate that in the absence of additional factors RNA polymerase does not terminate transcription at this site (M.R., unpublished). (4) Finally, the distribution of bases utilised in the third or 'wobble' position of the codons of *cro* is approximately random (there is a slight bias against G's and toward A's and C's). There are, however, pronounced A-T or G-C rich regions within the *cro* sequence (for example, the region between positions 114 and 134 is

91% A-T; the region between 168 and 179 is 75% G-C; and the region between 180 and 201 is 77% A-T).

It should be noted that the region of the lambda genome which encodes the Cro protein apparently serves as template for leftward transcription (from the opposite strand) into the *cI* gene during establishment of repressor synthesis relatively early during phage development<sup>12</sup>. Thus, the structural features noted above may reflect regulatory information involved in this transcription while concomitantly specifying the appropriate amino acid sequence for a functional Cro protein.

We thank M. Ptashne for helpful discussions, A. Johnson for making available plasmids containing *cro* gene and Alik Honigman for purified *AvaI* endonuclease. This work was supported in part by grants from the US NIH and NSF to M.P. T.M.R. is supported by an NIH postdoctoral fellowship.

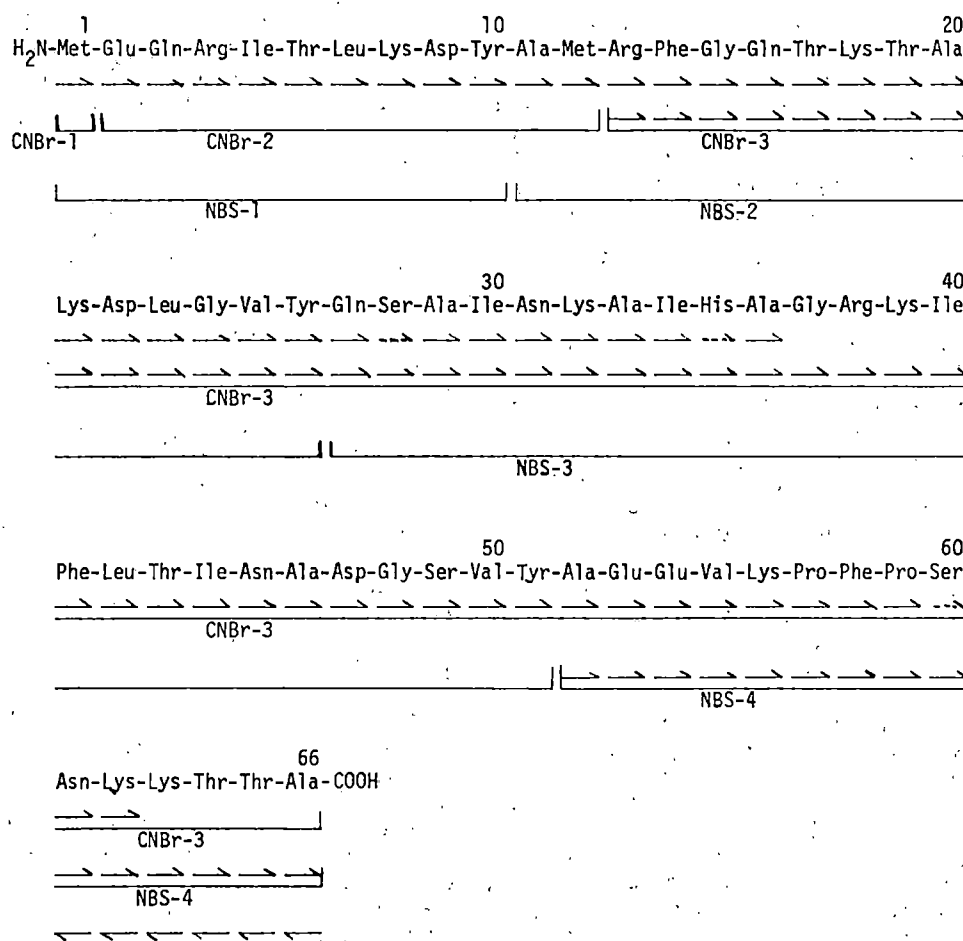

Fig. 3 DNA and protein sequences of the *cro* gene.

## Amino acid sequence of Cro regulatory protein of bacteriophage lambda

THE Cro protein specified by bacteriophage lambda is a repressor of the genes expressed early in phage development; this temporal regulation is required for a normal late stage of lytic growth (see refs 1–5). Cro protein has been purified and shown to bind to the operator regions, *O<sub>L</sub>* and *O<sub>R</sub>*<sup>6,7</sup>, used by the *cI* repressor protein to maintain lysogeny<sup>8</sup>; purified Cro also represses RNA synthesis initiated at the early promoter sites on  $\lambda$  DNA<sup>7</sup>. Among the features that make Cro interesting for further biochemical study are its timed physiological action<sup>1–5</sup> and apparent role in regulation of DNA replication<sup>9</sup>. Cro is also convenient for structural analysis because of its extremely small size<sup>6,7</sup>. Here we report the amino acid sequence of Cro protein.

The complete amino acid sequence of Cro protein has been determined by Edman degradation<sup>10</sup> of the intact protein, and two series of peptide fragments, one derived from cyanogen bromide

**Fig. 1** The amino acid sequence of Cro protein of bacteriophage lambda. Peptides are designated as CNBr when derived from cleavage by cyanogen bromide or as NBS when derived from *N*-bromosuccinimide cleavage; they are numbered sequentially in the order which they occur in the protein. Residue positions determined by automatic Edman degradation<sup>10</sup> (→) or by hydrolysis with carboxy-peptidases<sup>20</sup> (←) are indicated with arrows. Amino acid sequence analysis was performed by using a Beckman automatic sequencer 890C and the Beckman DMAA peptide program. Identification of PTH-amino acids was by (1) gas-liquid chromatography<sup>17</sup> on a Varian gas chromatograph 1840 A; (2) high-pressure liquid chromatography<sup>18</sup> on a Waters Associates liquid chromatograph with  $\mu$ Bondapak C<sub>18</sub> column; (3) amino acid analysis after HI hydrolysis<sup>19</sup>.

cleavage and the other from *N*-bromosuccinimide (NBS) cleavage. Digestion of the whole protein by carboxypeptidases A and B<sup>20</sup> further confirmed the sequence on the carboxyl end. The results are shown in Fig. 1 and Table 1.

The proposed structure contains 66 amino acid residues with a calculated molecular weight of 7,351 and has methionine and alanine as its amino and carboxyl termini respectively. The primary structure is in complete agreement with the amino acid

sequence predicted from the DNA sequence of the *cro* gene (ref. 11; and G. Hobom, personal communication). The composition of Cro protein based on the proposed sequence is Asp<sub>3</sub>Asn<sub>3</sub>Thr<sub>6</sub>Ser<sub>3</sub>Glu<sub>3</sub>Gln<sub>3</sub>Pro<sub>2</sub>Gly<sub>4</sub>Ala<sub>8</sub>Val<sub>3</sub>Met<sub>2</sub>Ile<sub>5</sub>Leu<sub>3</sub>Tyr<sub>3</sub>Phe<sub>3</sub>Lys<sub>8</sub>His<sub>3</sub>Arg<sub>3</sub>, which is 12 amino acid residues less than the composition previously reported<sup>7</sup>. This difference is largely due to renormalisation. Careful reanalysis of Cro protein of the highest purity and renormalisation (based on alanine) gives a composition that agrees with the one calculated from the sequence within experimental error.

The rules of Chou and Fasman<sup>12,13</sup> have been applied to the amino acid sequence of Cro protein; these predict several alternating regions of  $\alpha$ -helix and  $\beta$ -sheet, consistent with an overall globular conformation.

Although Cro and cI proteins recognise the same operator regions of  $\lambda$  DNA, there is no extensive sequence homology between the two proteins<sup>14</sup>. This indicates that the two repressors were derived by parallel evolution rather than by partial duplication of one of the two genes. The very different chemical nature of the two repressors probably reflects the different physiological needs of regulation during lytic development or lysogeny<sup>1,2,7</sup>. Substantial biochemical differences have already been shown in the affinity of the two proteins for operator DNA<sup>7,8,15</sup> and in the effect of operator region mutations on their binding properties<sup>6</sup>. There is also no detectable sequence homology between Cro protein and the eukaryotic chromosomal protein, histone H2B<sup>16</sup>, despite the close resemblance of their amino acid compositions.

## Active transport of picrate anion through organic liquid membrane

SEVERAL studies<sup>1-3</sup> have examined the concentrative transport<sup>4</sup> of ions through bulk liquid membranes. The energy for the transport in these systems is the pH difference—the chemical potential difference of protons across the membrane. We describe here a redox reaction-driven transference system in which picrate anion, a lipophilic anion, moves not only against its concentration gradient but also against its electrochemical potential gradient through bulk organic solvent.

The apparatus is illustrated in Fig. 1. Two aqueous phases (L, left; R, right) are bridged by a dichloroethane layer (M) containing *N,N,N',N'*-tetramethyl-*p*-phenylenediamine (TMPD). The aqueous phase, L, contains an oxidising agent, ferricyanide, and R, a reducing agent, ascorbic acid. Figure 1 shows the typical data where the initial concentrations of picrate in L and R phases are the same ( $10^{-4}$  M). The M phase contains  $10^{-4}$  M TMPD which is not equilibrated with picrate before the experiment. An increment of picrate in R phase signifies its corresponding decrease in the L phase. The concentration of picrate in R phase was found to increase and that in L phase to decrease linearly with time after a

**Fig. 1** Concentration of picrate as a function of time. Initial concentration of picrate was the same in L and R phases ( $10^{-4}$  M). The experimental chamber used was essentially the same as a U-shaped glass tube and is illustrated schematically in the inset. The volumes of the aqueous solutions designated as L and R are 15 ml and that of the organic bulk phase, M, is 40 ml. All three phases were agitated with a pair of glass stirrers at a speed of 180 r.p.m. The concentration of picrate was determined spectrophotometrically. The experiments were performed in a dimmed room to prevent light-induced degradation of TMPD. ○, Time course of changes in picrate concentration in R phase with the bulk phase not pre-equilibrated with picrate before the experiment. The aqueous phase on the L side contains 10 mM potassium ferricyanide and the R side, 10 mM sodium ascorbate: both solutions were buffered at pH 9.4 with 100 mM  $\text{Na}_2\text{B}_4\text{O}_7\cdot\text{HCl}$ . Because ferricyanide interfered with the spectrophotometrical determination of picrate, we determined the concentration of picrate in only R phase. The broken line is the calculated value of picrate concentration in L phase. ●, Data obtained with the organic phase equilibrated with picrate. The method of preparation of the membrane is as follows. A given amount of TMPD·2HCl was dissolved with minimal volume of distilled and deionised water (about 0.5 ml), which was poured into 40 ml of sodium picrate ( $10^{-4}$  M) buffered at pH 9.4 with 100 mM  $\text{Na}_2\text{B}_4\text{O}_7\cdot\text{HCl}$ . The free TMPD and the  $\text{TMPD}_{ox}^+ \cdot \text{picrate}^-$  pair in the solution prepared as above were extracted into 40 ml of dichloroethane, which was washed again with picrate solution ( $10^{-4}$  M, pH 9.4). The organic solution was used as the barrier phase, M after the separation of two phases. Other experimental conditions were virtually unchanged. The rate of transference was independent of pH in the range pH 6.5 to 9.5. The pH was adjusted with phosphate or borate buffers (100 mM). □, Transport with voltage clamp at 0 mV. Other conditions as above.

short lag period, and finally a steady state was reached. Picrate was transferred from L to R phase against its concentration gradient.

The lag period became shorter or was absent when M phase had been equilibrated with picrate before the experiments. The slope of the linear portion was approximately equal to that obtained without prior equilibration. All experiments described below were performed using pre-equilibrated dichloroethane. The method of preparing the bulk phase (M) is described in Fig. 1 legend. Figure 2 shows the rates of picrate transport in conditions of varying concentrations of ferricyanide, ascorbate and TMPD. The rates increase with increase of the concentrations of these agents and reach approximately the same plateau level.

The membrane potential has been shown to be important in transport across membranes<sup>4-6</sup>. In the case shown in Fig. 1, the electromotive force (e.m.f.) was initially 160 mV, rapidly decreasing to reach a steady value of 120 mV with the polarity being positive in R with respect to L phase. The e.m.f. acts in the same direction as the picrate flux and hence it is possible that it might be responsible for part of the observed flux. To examine the role of the membrane potential, we clamped the potential difference between R and L phases at 0 mV by short-circuiting a pair of calomel electrodes inserted in L and R phases<sup>7</sup>. This made no difference to the observed results; that is, the membrane potential does not contribute to the transport of picrate in this system. This implies that picrate is being transported against its electrochemical potential gradient, that is, that the transport of picrate in this system is 'active'<sup>8</sup>.

Our results can be explained by the following mechanism. At the L interface, TMPD is oxidised to a cation<sup>9,10</sup>,  $\text{TMPD}_{\text{ox}}^+$  which serves as a carrier for picrate anion,  $\text{picrate}^-$ . The  $\text{TMPD}_{\text{ox}}^+$  and  $\text{picrate}^-$  ion pair migrates down its concentration gradient within M phase. As the ion pair reaches R, picrate is extracted into aqueous phase by virtue of a discharge of  $\text{TMPD}_{\text{ox}}^+$  due to the reducing agent. The neutral reduced form of  $\text{TMPD}_{\text{red}}$  diffuses back to the interface and the process is repeated. Structures of  $\text{TMPD}_{\text{ox}}^+$  and  $\text{TMPD}_{\text{red}}$  are given in ref. 10. The importance of charging-discharging process of TMPD by the reduction-oxidation reaction is also suggested by the fact that in

acidic solutions, the rate of transference slowed down appreciably (data not shown). This may arise from protonation of reduced TMPD,  $\text{TMPD}_{\text{red}} \text{H}^+$  possibly as a result of the lack of the charging-discharging process. The decrease in L phase and the increase in R phase of a negative charge resulting from the transfer of picrate<sup>-</sup> from L to R are counterbalanced by the production of negative charge of  $[\text{Fe}(\text{CN})_6]^{4-}$  from  $[\text{Fe}(\text{CN})_6]^{3-}$  in L phase and by that of  $\text{H}^+$  associated with the oxidation of ascorbate in R phase, respectively.

The transport of cations<sup>1,3</sup> and amino acids<sup>2</sup> against their concentration gradient by coupling to a movement of the other ions in the opposite direction has been reported. It should be noted that no ion is co-transported or counter-transported in the system described here and that the energy for transferring picrate is supplied directly by the free energy associated with the chemical reaction. The substrate to be transported in this system is not restricted to picrate—any lipophilic anions capable of forming lipid soluble in pairs with  $\text{TMPD}_{\text{ox}}^+$  may be transported. It may eventually be possible to prepare a membrane system in which a specific substance is transported by coupling of a chemical reaction.

## Immunological sourcebook

Elizabeth Simpson

*Lymphocyte Differentiation, Recognition and Regulation.* By David H. Katz. Pp. xiii+749. (Academic: London and New York, 1977.) \$42; £29.80.

THE scope of this book is no less than a review of the whole of current basic immunology. This is approached under a series of chapter headings dealing with the surface antigens of T and B cells and their respective ontogenies; receptors and specificity of these two major subclasses and their functional properties; regulatory interactions in immune responses, including genetic control and the role of the major histocompatibility complex; and finally, immunological tolerance.

This is a monumental assignment for one person to undertake. Two thousand three hundred references are quoted, most of them published since 1970. Dr Katz's approach has been to consider his selection of the relevant references under the headings he has chosen, in many cases quoting substantial details of the work under discussion. In chapters where he has integrated the results of several papers and the views of different authors, the story emerges as an interesting one, and his own views are illuminating. This successful approach is seen most in the chapters dealing with T-B cell cooperation, a field in which the author has been extensively engaged. One can argue with him as to his choice of relevant references, and the reservations, many times reiterated, with which he regards data gathered from *in vitro* systems, but the overall synthesis of these chapters is good; they are both informative and provocative.

The chapters dealing with subjects outside the author's own experimental field suffer from repetition and a lack of synthesis of the data and in the discussion presented. Some sections read like a catalogue of papers; for example, the section on H-2-restricted cytotoxic responses describes sequentially and in great detail each of the examples (this class of response to virus, hapten and minor transplantation antigens), and fails to underline the essential similarity of the systems and

the important biological implications of the findings. The general lack of cross-referencing, either in the text, or by way of the index (which is totally inadequate) is most noticeable and irritating in chapters which proceed by cataloguing rather than by synthesis. For example, the question of the biological importance of polymorphism in the major histocompatibility complex (MHC) comes up in the chapter on T and B lymphocyte surface antigens in the sub-section on biochemistry of MHC antigens (p78), in the chapter on "Functional Properties of T Lymphocytes" during consideration of H-2-restricted cytotoxic responses (pp 281-296) and in the chapter on genetic control of immune responses (p530 *et seq.*); and yet there is no cross-referencing of the discussions therein.

The organisation of the chapters under the chosen headings has led to some loss of clarity. This is particularly evident in the chapter entitled "Functional Properties of T Lymphocytes" subdivided into (A) "Regulatory T Lymphocytes" and (B) "Effector T lymphocytes". Such a classification, which quite arbitrarily considers helper and suppressor T lymphocytes under the first heading and mixed lymphocyte reaction proliferative T cells, cytotoxic T lymphocytes and T cells mediating delayed type hypersensitivity under the second, obscures the distinction between precursor T cells for any particular function and effector cells which have differentiated as the result of exposure to antigen. The distinctive phenotype of the precursor cells for each function has been documented from many laboratories using anti-Ly antiserum, and implies a precommitment to function before encounter with antigen. This data on precommitment is contained in several of the references quoted in the bibliography but Dr Katz makes only brief mention of the notion, quoting just one of the references in a manner suggesting that it contains the only data available on the point (p265).

In a different context Ly phenotyping is mentioned under the heading of "Surface Phenotype Antigens" (chapter VIII) and in the chapter on

"Surface Markers of T Lymphocytes" (chapter II). Discussion of the data, however, is scattered in the text, and these are not used to integrate earlier, inevitably less well defined observations on the separation of functional subsets of T cells. In some cases, as in the chapter on "Ontogeny of T Cells", they are not mentioned at all.

Chapters X, on "Regulatory Cellular Interactions", XII on "Genetic Control of Immune Responses" and XIII on "Mechanisms of Regulatory Cellular Interactions" obviously contain overlapping material. In some cases, the division chosen has fragmented and obscured the story; for example, the failure to follow through the discussion on T-B cooperation in chapter X with the data on factors, which is presented in chapter XIII. The factor chapter (XIII) itself is incomplete in as much that the genetically restricted factor of Erb and Feldmann is mentioned not here, but in the previous chapter, to which there is no cross-reference on this point, and the suppressor factor of Kontiainen and Feldmann is not mentioned at all.

There are some misquotations of references, some by omission (that is, failing to take account of the whole of the contents of a paper, in some cases, stating that the author(s) had not looked at a particular point, when they had done so) and some by addition (that is, fanciful addition to the data); but this must be almost inevitable when so many references are considered, and does not occur often enough to mar the value of the text and its very extensive bibliography for serious readers. Informed immunologists will be able to seek out the discussion and references they want by assiduous detective work which would not have been necessary had the index been adequate and the cross-referencing in the text more thorough. For less informed readers—for example, graduate students—this valuable sourcebook and bibliography will not be so accessible. □

## Nutrition and the brain

*Nutrition and the Brain*. Vol. 1: Determinants of the Availability of Nutrients to the Brain. Pp. xi+324. Vol. 2: Control of Feeding Behaviour and Biology of the Brain in Protein-Calorie Malnutrition. Edited by Richard J. Wurtman and Judith J. Wurtman. Pp. 313 (Raven: New York, 1977.) £19.50 each volume.

A NUMBER of years ago a distinguished neurochemist remarked that if people continued to take up neurochemistry at the rate obtaining at the time, then everyone in the world would be a neurochemist long before the end of the millennium. The rate at which books about nutrition and the brain have recently appeared seems to threaten a comparable natural disaster; and here are two more. The fact that your reviewer seems to be one of the few workers in the field who has not yet found the energy to produce one, may be the reason for a certain weariness, if not sourness in his approach and a developing propensity for denunciatory overstatement. But at least it will be agreed that a field with so much contemporary competition demands more than usual justification from the late arrivals.

Someone, somewhere, will find almost all of them very useful; but unfortunately the very misleading title of the series, *Nutrition and the Brain*, will not lead the literature surveyor to many of the better chapters unless they appear separately in the indexes under such headings as 'Cerebral Energy Metabolism', 'The Natural Diet of Primates', and so forth. However widely one interprets the word 'Nutrition', and however all-pervasively 'the Brain' controls the rest of physiology, the Editors have surely assumed too readily that their subject encompasses the whole of nutritional biochemistry and neurobiology.

Thus, if the young scientist entering the field happens to be fascinated by evolutionary aspects of the natural diet of Primates, then he will be as entranced as was your reviewer by the erudition of the first long chapter. But who is to blame him if he reflects that all the mammalian orders grow remarkably similar brains (in compositional and metabolic terms at least) whether they are gatherers or hunters, carnivores or vegetarians, ruminants or rodents; and that these matters are therefore unlikely to concern him. If he is a neurochemist, he will already have read one of Sokoloff's other excellent accounts of cerebral energy metabolism. If he is not, I suspect he

will not be much helped, even by such a classic account, until we reassure him that the subject is not one which bears at all directly on the problems of the starving billions or overstuffed millions of this wicked world.

The chapter on amino acid availability to the brain may at first sight seem more relevant, especially to those who have not yet caught up with the 'protein fiasco' and still believe that what the Third World needs most of all from us is steak. The whole topic of the blood-tissue relationships of the brain with regard to amino acids is a marvellous one for those interested in transport mechanisms or in certain in-born errors of metabolism. It is, however, of no direct interest in the present context.

It has been known for some time that certain putative neurotransmitters are synthesised within the brain from particular precursor amino acids; that the blood levels of these latter influence the brain levels of the former and are themselves influenced by dietary intake. It therefore persuasively follows that in this particular instance, something about the diet influences substances which are held to be to do with sleep, or mood, or otherwise with neurotransmission. This leads by delightful prestidigitation to the argument that since, under *in vivo* conditions, one metabolic pathway in the brain can be shown to be controlled by precursor substrate concentration; and since the latter is often derived from dietary sources, then who knows but that all the other metabolic pathways may not ultimately be under nutritional control as well? We can therefore discuss as many of them as we please. I suppose it depends what you mean by "ultimately". If this kind of argument persuades you of the relevance to 'Nutrition and the Brain' of its energy metabolism; of amino acid, folic acid, B<sub>12</sub> and choline availability to the tissue, and of the role of B vitamins in nervous function, then these books are for you; but not, I fear, for me.

You may even be interested in the blood-brain barrier, other than as a convenient incantation for writing off phenomena which are otherwise difficult to "explain". In that case you can choose between chapter 2 in which the BBB is responsible for the brain's metabolic idiosyncracies but whose nature and location are uncertain; and chapter 3, in which the anatomical site is no mystery to the author and its properties quite well enough defined to "explain" a hopelessly mixed bag of transport mechanisms; and chapter IV which gives us yet another point of view on what may be the best-preserved neurobiological hoax of the twentieth century. At least the impartial reader

will not be lulled into complacency by any uniform consensus, and the hunt will continue for some kind of impermeable wash-leather separating the blood from the brain.

Volume 2 gets prematurely bogged down in a discussion of the control of eating behaviour in 145 pages with 827 references, as if the main elements of the main title (*Nutrition and the Brain*) have in some way become juxtaposed. The remaining three chapters, however, at last get down to the matter in hand. A chapter on the effects of undernutrition on brain morphology is mostly, and properly, about influences on brain development, although the authors complain that there is no information about the adult state in this respect. Could it not be that there is nothing interesting to see in the brains of starved adults (except in those exceptionally rare encephalopathies so beloved of the last chapters in tomes on clinical neurology)? I happen to think that in this whole, surprisingly lesion-free neuropathology of developmental undernutrition, the most rewarding contemporary growing-point may lie in current attempts at quantitative neurohistology. So, it is a bit disconcerting to be quoted here as not thinking much of the idea. There are some formidable technical obstacles to be overcome, however, before brain structures can be realistically counted, so that the whole of world knowledge in this area could be summarised on half a page with about four references; thus, it is perhaps to be expected that this chapter too dwells on matters outside its stated subject, or fills in the pages by reproducing chunks from elementary textbooks of neurohistology.

The second half of volume 2, however, blossoms forth with two quite outstanding chapters on the effects of widespread varieties of malnutrition on biochemical aspects of brain development, and on human behaviour. Both are masterpieces of clarity: the first in systematically describing what we know without ambiguity; the last in making it perfectly clear that there is no more difficult and confusing topic than the effects of infant malnutrition on human behaviour. The first, by Nowak and Munroe will be a classic reference point for a long time to come. The last, by Pollitt and Thomson should be a powerful antidote to those politicians and the less perceptive of their scientific advisers who still persist in that simplistic non-question, "Does infant malnutrition cause mental retardation?"

## Low temperature physics

*The Quest for Absolute Zero: The Meaning of Low Temperature Physics.* Second edition with SI Units. By K. Mendelssohn. Pp. 281. (Taylor and Francis: London, 1977.) £5

Low temperature physics, for those who know little of it, often seems to represent the very epitome of scientific futility: a seemingly purposeless (and highly expensive) competition to see who can approach most closely the unattainable absolute zero of temperature. They should read this book. It would be very likely to change their minds since, as an apologia for one of the most fascinating and fruitful areas of physics to emerge this century, it could hardly be bettered.

Mendelssohn sets low temperature physics squarely in its historical and scientific context, close to the centre of the stage during that quite unprecedented explosion of knowledge which took place in physics in the early decades of the present century. Using an entirely non-mathematical approach, he explains with impressive clarity and accuracy how many of the fundamental concepts of modern physics arose from, or were illuminated and supported by, experiments on the novel states of matter which exist at very low temperatures.

The first four chapters are largely historical in structure, the story opening with Cailletet's liquefaction of oxygen (90K) in 1877, running on to describe the liquefaction of hydrogen (20K) by Dewar in 1898. This first section ends with an assessment of the achievements of Kamerlingh Onnes who, by liquefying helium (4K) in 1908 and discovering superconductivity, became the father of low temperature physics as we know it today. This section includes explanations of the isotherms of real (non-ideal) gases, critical points, cascade liquefiers and expansion engines.

Unusually, Mendelssohn considers how the personal attributes of the researchers may crucially have influenced the extent of their scientific achievements. For example, Dewar, portrayed as a brilliant but autocratic and quarrelsome loner, failed in his attempt to liquefy helium. The prize fell, instead, to the much more open, equable and diplomatic Onnes who possessed the inclination and ability to create a scientific laboratory in the modern sense, successfully coordinating the activities of a comparatively large complement of technical staff, colleagues, and visitors from other universities.

The next five chapters include vigorous and readily understandable accounts of topics such as the Third Law, heat, entropy, zero point energy, low temperature specific heats, quantisation, radiation, indeterminacy, gas degeneracy, quantum statistics of ideal gases, Fermi surfaces, Curie's Law, magnetic cooling and the various ramifications of superconductivity. Individual contributions to the developing conceptual structure made by such figures as Bohr, Born, de Broglie, Einstein, Fermi, Heisenberg, Nernst and Schrodinger, many of whom were known personally to the author, are carefully described and assessed.

At this point, the second edition diverges from the original, published in 1966. A whole chapter is now devoted to cryogenic technology, dealing with SQUIDS (superconducting quantum interference devices, used for measuring tiny magnetic fields), computer elements, superconducting motors and generators and, of course, superconducting magnets. The final chapter, on superfluidity, has also been extensively reworked to take account of recent advances, particularly in the new and rapidly growing field of superfluid helium-3. Even so, the pace of current cryogenic development seems

to have outstripped production of the book which, for instance, describes dilution refrigeration as capable of "temperatures approaching 0.01K in continuous operation", whereas 0.003K is now routinely being reached by this technique at Grenoble.

The coloured line drawings are helpful. There are also a number of photographs portraying most of the major scientific figures discussed in the text: of particular note is one entitled: "The heyday of low temperature physics. L. D. Landau in discussion with the author in Moscow, 1957."

As might be expected in a work with this breadth of vision, containing so much of the author's personal viewpoint of the scientific world, pungently and entertainingly expressed, there is much with which practitioners may take issue; but this in no way detracts from the success of the book as a whole. Like the previous edition, it can confidently be recommended to anyone who would like to know more about the behaviour of matter in that unimaginable abyss of coldness around and below 1K.

## Mammalian development

*Developments in Mammals.* Vol. 2. Edited by Martin H. Johnson. Pp. 241. (North-Holland: Amsterdam, New York and Oxford, 1977.) Dfl. 72; \$29.50.

THE second volume in this interesting and timely series continues in the style and format established in the first. There are both good and bad aspects to this. It was hoped that the small and inadequate typeface would have been improved but this volume is also difficult and tiring to read. Such is the speed with which these two volumes have been produced that the changes in typeface could not be introduced in volume 2. I for one look forward to their introduction in the next issue.

The good balanced mixture of developmental biology, reproductive physiology and biochemistry has been maintained. Two papers concern growth and maturation of oocytes, and transport and selection of sperm. These are followed by three papers each considering the cleavage stages of rodent development from slightly different viewpoints. This section is particularly welcome as the subject is somewhat controversial, with much circumstantial evidence concerning determination and differentiation of the two cell lines which emerge during cleavage. Here, in these three papers, all the

evidence is reviewed, and the various interpretations that have been put on the data are well discussed. Of the remaining four papers, one reviews the *in vitro* culture systems and their application to the peri-implantation period, whereas the other three address another hotly controversial subject—the involvement of steroid hormones in controlling implantation and in particular to what extent the mammalian blastocyst may produce steroids and thus perhaps control, at least in part, its own implantation.

Encouraged by editorial policy, authors have occasionally been speculative and have also used the book as an outlet for previously unpublished data. Although this policy has obvious advantages in publications such as this series, there are hazards since papers are edited rather than refereed, and somewhat one-sided arguments occasionally slip through the net. In this second volume, the editor has provided the best possible answer to this problem by gathering together several papers on one subject, thus presenting argument and counter-argument side by side. For scientists new to the field, this is especially useful. Although expensive, this volume is good value and augurs well for the next of the series.

## Shallow layers of the Continental Shelf

*Exploring the Geology of Shelf Seas.* By R. McQuillin and D. A. Ards. Pp. 234. (Graham and Trotman: London, 1977.) £10.50.

As with many books, the title is a little misleading. Although the subject matter is concerned with general techniques that may be used in mineral or even oil exploration, it would be incorrect to say that the book is concerned with exploration specifically. The NERC/IGS, of which the authors are members, uses the techniques described more as mapping devices than as exploration tools.

The purpose of the work is to describe how information about the shallow layers of the Continental Shelf down to about 300 metres or beneath Quaternary cover, may be obtained. Over the past decade, considerable attention has been given by the oil companies to the "deep geology" of the North-West European Continental Shelf resulting in the discovery of major oil and gas fields in almost every geological formation from the Carboniferous to the Tertiary. In contrast, however, very little is known of the near subsurface, and there are hardly any maps or data published on this topic, even by the IGS who have by their own confession done the most work. There is thus a large gap in our knowledge about the nature and extent of bottom sediments. This is the region with which the IGS is concerned and on which the book concentrates.

Seven of the chapters are devoted to geophysical techniques and only one to the acquisition of geological information by sampling and drilling. This tends to give the book a basic imbalance, and it is often not fully clear how the results of geophysical work are utilised by the geologists in making maps. Just such an account would have placed the book in perspective. Nonetheless, the book is clearly written and the reader should have little difficulty in understanding basic principles even if he is left a little in doubt as to the usage of the methods.

The opening chapter deals with the problems of position fixing at sea. This is a useful chapter by itself, as it is often difficult to find concise accounts explaining the various methods. Once at sea, two sorts of observation may be made. The first area is the sea itself, and the nature of the seafloor; the second, the strata beneath the sea bed, from which information may be

obtained either directly or indirectly. Ways of studying the former using echo-sounding and side-scanning solar techniques thus follow, but by far the greatest emphasis is placed not unnaturally on the latter: gravity and magnetics, but particularly continuous seismic profiling techniques, both sub-bottom-sparker—and deep penetration seismic. These tools, perhaps above any others, have provided the means of mapping large areas using relatively few geological control points.

Although well intended, the chapter on sampling methods does not fully relate to the rest of the book, and is itself somewhat disjointed, reading

## Planetary atmospheres

*The Physics of Atmospheres.* By J. T. Houghton. Pp. xiii+203. (Cambridge University: Cambridge, London, New York and Melbourne, 1977.) £6.50.

PROFESSOR HOUGHTON has written a most interesting book with the intent "to introduce physics students at both undergraduate and graduate levels to the physical processes which govern the structure and circulation of a planetary atmosphere." He is completely successful. The book is very strong on the aspects of radiative transfer, as might be expected because Houghton's group is the world leader in this field. Chapter 2, "A Radiative Equilibrium Model", and chapter 4, "More Complex Radiation Transfer", are completely devoted to radiative transfer; the latter includes a most valuable discussion of how to proceed from molecular properties, such as line widths, to computations of radiative heating rates in realistic atmospheres. Chapter 5, "The Upper Atmosphere", also focuses on radiative transfer and contains a unique detailed treatment of the breakdown of thermodynamic equilibrium. Chapter 6, "Clouds", is mainly concerned with their radiative properties.

Chapter 7, "Dynamics", chapter 8, "Atmospheric Waves", and chapter 10, "The General Circulation", provide an excellent introduction to the role of the large scale motions in governing atmospheric structure. I found the approach here, and in chapter 9, "Turbulence", straightforward and efficient. It reminded me of some very clear lectures on the subject that I heard from Dr John Green of Imperial College in 1971. Houghton acknowledges a set of dynamics' lectures by Dr R. S. Harwood who was formerly associated with Dr Green. From these chapters, the student could easily tackle the more advanced texts on atmospheric dynamics.

Chapter 3, "Thermodynamics", in-

*Nature* Vol. 270 17 November 1977

more like a catalogue than an explanation of how geophysical data is used to site sampling and drilling locations, or indeed of how maps are constructed.

One cannot hope, however, for everything, and the book will be of value in explaining little-known facets of geophysical techniques to students of the earth sciences who might otherwise find it difficult to locate the information.

John Brooks

*John Brooks is Senior Geologist in the Petroleum Engineering Division of the Department of Energy, HM Government, London, UK.*

cludes a treatment of available potential energy as crystallised by Lorenz. This concept is carried, too, in later chapters and is most valuable in explaining structure. I have used it myself in lectures on the physics of the upper atmosphere. One can most easily perceive from this approach that the observed structure is the result of a continuous interplay between radiative and dynamical processes.

Chapter 11, "Numerical Modelling", and chapter 12, "Global Observation", again stress the radiative transfer aspects. Chapter 13 has the longest title of all, "Atmospheric Predictability and Climatic Change", but consists of only two pages of text and three figures, and seems to be an unnecessary afterthought which is not at the same level as the rest of the book. Chapter 6 is also a little too short to catch the essence of the physical aspects of clouds. These are, however, minor complaints, for the book as a whole is very well written, and does not pretend to provide all of the physics of atmospheres.

I learned much from working through some of the examples (provided with solutions) which are an integral part of the text. The interested student could, in fact, teach the subject to himself with the text, the useful information in the appendices and a hand-held calculator. Although references are provided, little from them is needed to work through the text. I recommend the book to all physics students interested in atmospheres. To all physics students, the text presents live examples of the laws of physics, which may replace the older examples of steam engines and ice skaters. Many first-year meteorology students would also benefit from working through this text. An early overview of the subject might be very helpful before immersion in two years of concentrated courses at the graduate level.

Reginald E. Newell

*Reginald E. Newell is Professor of Meteorology at the Massachusetts Institute of Technology, Cambridge, Massachusetts.*

## Quirks and strong points

*Psychologists on Psychology.* By David Cohen. Pp.360. (Routledge and Kegan Paul: London and Henley, 1977.) £6.95.

PSYCHOLOGY nowadays is a very mixed bag, and indeed some would query whether it is really just one bag. David Cohen's book, which is a series of interviews with successful psychologists, illustrates very well how far apart from one another they are. It is not so much that they disagree, though disagreements there are in plenty in this enterprising book. What is much more striking is that the different psychologists featured in this book are often so far apart in their subject matter, their approach, their conceptual frameworks, and their aims, that even mutual criticism is out of the question.

The interviews which David Cohen

gave to these stars of the behavioural world seem to have been well planned, and the questions are searching enough to bring out the subject's quirks as well as their strong points. Perhaps Cohen should have been more critical but even here there is an advantage of some interest, because the calmness of the interviews seems to have brought out into the open a staggering complacency in some of the psychologists concerned.

David Cohen's attempts at the beginning and end of the book to find some link between the backgrounds and personalities of the different interviewees—a psychology of psychology—are almost certainly ingenuous; these people are as diverse as their work. The interviews which form the core of this book, however, give a clear, conveniently quick though often disquieting picture of what many of the present leaders of psychology think they are up to.

**P. E. Bryant**

*P. E. Bryant is Lecturer in Psychology at the University of Oxford, UK.*

## Androgen action

*The Mechanism of Action of Androgens.* By W. I. P. Mainwaring. Pp. x+178. (Springer: New York and Berlin, 1977.) DM65.40; \$28.80.

THIS is a useful monograph written by an acknowledged expert in the field of androgen action. The book is an attempt to describe the molecular events associated with the entry of testosterone into androgen-sensitive cells and the subsequent metabolic changes associated with the presence of the hormone in these cells.

The author uses a temporal approach to the problem of the analysis of androgen action and, as usual, much of the material is drawn from experiments on the rat ventral prostate. The author is careful to point out the reservations which must be applied in generalising from this animal model to any other species or tissue.

The core of the book is devoted to an account of the initial events and the early and late events associated with androgen stimulation of target tissues. The author points out that, although androgens influence transcription and the synthesis of RNA, they may also affect other processes. The manner in which androgen metabolism in the target tissues influences the mode of action of androgens is considered in detail. The high affinity binding sites,

the intracellular transformation and the subsequent nuclear retention of the hormone are reviewed. The need to isolate and characterise the androgen receptor proteins is stressed. It is a pity that the author did not devote more attention to the effects of androgens on muscle and perhaps develop a working hypothesis or speculate on how they may affect this large body mass.

In the latter part of the book, the author critically reviews his own studies showing that some of the actions of androgens are explicable on the basis of the increased production of selected mRNAs and ribosomes. Thus, androgen action is at least in part an enhancement of genetic transcription.

The author writes: "The halcyon days of studies on the mechanism of action of androgen are drawing to a close." In fact, this excellent text is a clear indication that this is not so. Future research on the mode of action of androgens may, however, require more sophisticated approaches and more elegant tools. The book is clearly written and the reader gets the impression of being led through some of the mysteries of androgen action as in a series of lectures. The text has the stamp of authority. It is written by a scientist who has in fact uncovered many of the interesting facts on the mode of action of androgens. The book will be valuable to researchers and to university teachers concerned with the mode of action of steroid hormones in general and androgens in particular.

**G. S. Boyd**

*G. S. Boyd is Professor of Biochemistry at the University of Edinburgh, UK.*

## Geomorphology and remote sensing

*Remote Sensing in Geomorphology.* By H. Th. Verstappen. Pp. x+214. (Elsevier Scientific: Amsterdam, New York and Oxford, 1977.) Dfl.98; \$39.95.

THIS well produced book will be valuable to the postgraduate or advanced research worker, rather than as an undergraduate textbook. A large amount of material is covered in a somewhat condensed style. Perhaps one of the chief merits of the book lies in its extensive bibliography of sources in English, German, Dutch, Russian and French languages. Of the 214 pages, approximately eleven are close printed lists of references, although some sources seem to have too brief a description, which may not be sufficient for procurement.

The pages are a source of constant stimulus: a technique or idea is introduced, and briefly described, but the reader will have to go to the original source for full details. This is perhaps a natural result of a text from an authority with the length and breadth of experience of the author.

The illustrations are plentiful and well produced. Some are in colour, and a notable feature is the number of stereopairs printed side by side for viewing with a pocket stereoscope.

Subjects covered include an historical introduction, a description of the types of imagery available, and available methods of interpretation. Chapters are devoted to image analysis based on relief (stereoscopy) and density criteria; pattern and texture are subsumed within these headings.

Geomorphology itself is divided into genetic and environment divisions, the latter including treatment of land systems methods of survey. This means that environments and major zones such as coastal, glacial, tropical and fluvial are discussed using examples hard upon one another's heels, with photography, radar, thermography and satellite imagery also intermingled. The examples used include lunar and planetary geomorphology. A final chapter deals briefly with such vital items as relative costs and fieldwork methods.

This is a most stimulating book, but one to be dipped into and used for reference or browsing. Because of the condensed staccato style, however, it is somewhat indigestible.

## Biochemistry and pharmacology of venoms

*Venoms: Chemistry and Molecular Biology.* By Anthony T. Tu. Pp. 560. (Wiley-Interscience: London and New York, 1977.) \$43; £25.90.

VENOMS have always had a peculiar fascination. How do they kill animals (and, in particular, humans)? What do they contain, and can any of the components be put to use either as tools in research or as therapeutic agents? Before the advent of modern chromatographic techniques, not much progress could be made in the field but since then there has been (to say the least of it) no shortage of papers. The quality of some of these has, however, been exceedingly bad. Separation procedures still require some skill and if the skill is lacking they lead to unspecified mixtures. The desire to inject such mixtures (or, indeed, whole venoms) into animals and see what happens is (apparently) strong. It ought always to be firmly resisted.

All of this means that to write a book on venoms is a formidable undertaking. It needs a considerable knowledge of the relevant aspects of chemistry, biochemistry and pharmacology and, if one is to deal with the effects of venoms in humans, of clinical medicine as well. Enough to daunt the strongest spirit. Professor Tu admits this in his preface and uses the phrase "monumental task". He has, in the event, produced a book containing over four hundred pages devoted to snake venoms (his own research interest) and rather less than one hundred to other animal venoms (scorpions, bees, wasps, and so on). One could hold the view that this is a trifle unbalanced, since (for example) the components of bee venom have been extensively investigated both chemically and pharmacologically. On the other hand, it is true that a bewildering variety of peptides and proteins have been found in snake venoms and some of these have proved to be extremely useful. For example, the phosphodiesterase contained in many snake venoms is an invaluable tool in the determination of nucleotide sequences in nucleic acids. On these grounds, the long section of the book on the enzymes present in snake venoms can, no doubt, be justified.

I must confess, however, that I found the book to be essentially uncritical. Most of the papers quoted seem to be given equal weight when clearly some of them (all too many, I fear) are un-

satisfactory on chemical or biological grounds or both. What, for example, is the point in giving a list (p509) of the values reported for the (so-called) LD<sub>50</sub> of apamine in mice when it is perfectly clear that the correct value is that given by Habermann (in 1972, incidentally, and not as quoted) and subsequently confirmed by other workers? How does one feel about the (supposed) component of bee venom called "cardiopep"? Ought one not to entertain the suspicion that the biological effects ascribed to it are really due to noradrenaline (shown to be present in the venom, as distinct from the venom gland, by Banks *et al.*, 1976, and not, as given, by Owen, 1971)? Again, what about minimine? This is certainly my favourite substance (or non-substance) because its biological activity is supposed to be the produc-

tion of miniature flies from the larvae of *Drosophila melanogaster* (whoever would think of such an experiment?) One could continue, but the list of doubtful substances and even more doubtful biological activities would be long and tedious. In defence of Professor Tu, I must say that, in my view, no one man could read and assess critically all the literature in this area.

It is a pleasure to be able to say that the book is well produced, well laid out, and that the references are remarkably up-to-date and (for the most part) remarkably complete. The book will certainly be of value (if only for the references) to workers in the field and to those wishing to enter it.

C. A. Vernon is Professor of Chemistry at University College, London, UK.

## Basic statistical handbook

*A Handbook of Numerical and Statistical Techniques.* By J. H. Pollard. Pp. xvi + 349. (Cambridge University: Cambridge, London and New York; 1977.) £13.50.

WHEN books on basic statistics continue to appear with amazing regularity, it is refreshing to find one which more than permutes the 'usual material'. This book not only describes essential statistical techniques but gives a welcome priority to elementary numerical methods.

The author aims to help computer users, firstly to understand the output of statistical packages, and secondly to adapt these and similar packages for programmable calculators to suit their own requirements. Although it is not a textbook of elementary numerical and statistical techniques, its uniformity and clarity of presentation, together with its comprehensiveness, should give it wide appeal. A basic knowledge of mathematics is assumed.

The contents have been skilfully divided into three parts. Part I (seven chapters), after a brief introduction to essential basic mathematics and a helpful discussion of sources of error, describes numerical methods for locating the roots of non-linear equations, data smoothing, integration, differentiation and interpolation. It finishes with a variety of useful techniques including the regrouping of grouped data, the fusing of smooth curves and steepest descent.

Basic statistical techniques, except regression, are presented in part II (seven chapters) which, after briefly

introducing probability theory, describes the important frequency distributions including the Pearson system. Two chapters devoted to hypothesis testing and point and interval estimation provide a broad survey of parametric and distribution-free statistical tests. Each test is presented in a standard format which facilitates both comprehension and correct application. This part ends with three special topics—random numbers, data transformation, and censored and truncated distributions.

Part III (four chapters), devoted to the method of least squares, describes simple linear regression (with and without matrix notation) and most of the associated statistical tests. (Unfortunately, the statistical comparison of two or more regression lines has been omitted.) Curvilinear and multiple linear regression are presented succinctly, using matrix notation, and this part ends with an introduction to non-linear regression.

Throughout the book, each technique is separately referenced and well illustrated with a fully-worked example, usually from the life sciences. Specialised tables are sensibly interspaced with the text, while those of more general application are placed in an appendix. Every chapter includes a selection of exercises though unfortunately the answers are not given.

This handbook has been carefully assembled, it is easy to use, and cross-referencing is kept to a minimum. It should be a valuable asset to the scientist and the statistician.

A. L. Johnson is a statistician in the MRC Statistical Research and Services Unit, University College Hospital Medical School, London, UK.

# obituary

## Bruce C. Heezen

PROFESSOR Bruce C. Heezen of the Lamont-Doherty Geological Observatory, New York, died on 21 June 1977 at the age of 53 of a heart attack while working on board the U.S. nuclear research submarine NR-1 studying the Reykjanes Ridge south of Iceland.

With his late colleague, Professor Maurice Ewing who was founder and director of the Lamont (later Lamont-Doherty) Geological Observatory, Bruce Heezen played a major part in the rapid post-war expansion of our understanding of the morphology and geology of the deep ocean floor, on which the now widely accepted theory of plate tectonics is based.

During the war the techniques for studying the deep ocean improved immensely so that in the early 1950s all sorts of new geological and geophysical data were being collected from the increasing number of research cruises. With Maurice Ewing, Bruce Heezen saw the enormous potential in the thorough compilation and analysis of these data, especially the morphology, on a world-wide scale. Because of the restrictive attitudes of the U.S. Navy on the publication of contour charts, he was forced to develop, with the cartographic skills of Marie Tharp, the physiographic diagram style of presentation of seabed morphology. These charts, several of which were published by the National Geographic Magazine, have been widely used by those interested in the oceans and have contributed significantly to an appreciation of what lies beneath the sea surface. His analysis of ocean floor morphology, initially of the North Atlantic and published as a Special Paper of the Geological Society of America in 1959 but later extended world-wide, became the basis of a physiographic classification used now by oceanographers, geologists and even by lawyers.

During these morphological studies in the late 1950s he made what I believe to be his greatest contribution to the earth sciences. He recognised that the major ridge systems which lay roughly in the centre of many oceans were in fact linked into one continuous, although sinuous, mountain range 40,000 miles long and covering an area equal to that of all the continents combined. He found that the axis of this mid-ocean ridge system was associated with shallow seismicity and was able to predict the existence of hitherto unknown ridges southeast

of Africa and across the Arctic ocean. Along the axis Heezen, and his colleagues Tharp and Ewing, noted a more or less continuous valley which was morphologically similar to and actually linked to the Red Sea and the East African rifts, and also to the tension cracks in the central Icelandic graben. It was clear that along this 40,000 mile axis the crust of the earth was under tension and splitting apart. Heezen saw this initially as evidence for an expanding earth but dropped this idea when the subduction mechanism was discovered to absorb the excess crust and global plate tectonic theory developed.

Although Heezen was able to view the oceans on a global scale, he was concerned with all scales of deep-sea geological processes. He recognised that far from being quiet passive regions, the abyssal deeps were disturbed by fierce and destructive turbidity currents which contributed to the cutting of submarine canyons, transported sediment great distances along the sea floor and which gave rise to abyssal plains. He was interested in all modes of sedimentation and pioneered the study of deep-sea bedforms, such as sand waves and dunes, and their relation to near-bottom ocean water movement. In his search for details of bottom processes he exploited the use of bottom photography to the full, superbly and readably presented to the general public in his book with Hollister, *The Face of the Deep* (1971) nominated for a U.S. National Book Award, and in the last decade he made numerous dives in research submersibles to observe the bottom directly.

Heezen was much concerned with the practical problems presented by the deep ocean. For years he advised the cable industry on the potential hazards to deep-sea cables from geological causes and much of his submersible work was directly related to naval requirements. He was an ardent supporter of international collaboration, especially the GEBCO bathymetric chart project, and pioneered the cartographic presentation of geological and tectonic data for the Commission for the Geological Map of the World.

Born in Iowa, Bruce Heezen obtained his bachelor's degree from the University of Iowa in 1948 and his Ph.D. from Columbia University in 1957. He joined Maurice Ewing in the formative stages of the Lamont Geological Observatory and spent his work-

ing life there, becoming assistant professor in 1960 and associate professor in 1964. He was an enthusiastic and hard-driving seagoing scientist dedicated to using ship-time to its fullest extent. In the same way he used his time ashore to the full, often hard at work until the small hours in his rambling and paper-filled house on the Hudson River and yet never too busy to devote time to his students. Neither did he stint himself in some of the pleasures of life. He was always good for a party, beaming, boyish in appearance and heavy in build. He had a strong and provocative personality, not mincing his words when he felt strongly about an issue, and it was tragic, but perhaps inevitable, that his early collaboration with the equally strong personality of Maurice Ewing should have changed into a bitter quarrel in which both parties as well as the science suffered.

Heezen's contributions to science have been recognised by the award of the Cullum Geographical Medal and the Francis Shepard Medal for excellence in marine geology, and in June this year by the award by the American Geophysical Union of the prestigious Walter H. Bucher Medal for his life's work of "original contributions to the basic knowledge of the earth's crust."

His loss will be keenly felt by his life-long collaborator, Marie Tharp, his many colleagues, friends and students, and by the whole marine geological community who owe so much to his energetic research, his insight into the deep oceans of the world and his inspiration of his students.

A. S. Laughton

## Howard Hinton

PROFESSOR Howard Everest Hinton FRS died on 2 August 1977, aged 64. He was one of the few remaining polymaths in the field of biology, having wide interests in many branches of the subject. However, he had a remarkable ability to become expert in any topic within a remarkably short time, so that few of his acquaintances, meeting him in connection with one facet of his interests, realised that this was not his major subject of study. Even his friends were often surprised by discovering his involvement in new fields of interest in science and the arts, as well as by his political naivety.

Hinton was born in Mexico, and his

reminiscences of his childhood suggested that his early education was far from conventional. It clearly did not allow him to achieve his academic potential, for he was not thought well grounded enough to enter the University of California at Berkeley, and had to content himself with admission to St José State College. However he so distinguished himself that he was soon able to transfer to the Berkeley campus. As a student he is said to have been aggressive and somewhat anti-social, with political attitudes and a concern for the underdog which, even at Berkeley, were forty years ahead of their time. Nevertheless he was clearly a brilliant student, and after taking his B.Sc. he moved to Cambridge, England to take his Ph.D. under the supervision of Dr A. D. Imms.

His main academic preoccupation at that time was beetle taxonomy, but his wider interests were already apparent. He went on scientific expeditions to his birthplace, Mexico, in 1933 and 1934, and in 1937 to Peru, Bolivia and Brazil. In 1939 he was appointed Assistant Keeper at the British Museum (Natural History) in London, first to work on what was to him the new subject of orthoptera (he soon made himself an expert) and then on the group which were still his main interest, beetles. He caused some concern to the authorities at the museum, for he was not prepared to adopt the gentlemanly working hours (10 to 5) then generally accepted. He slept—or worked—night after night in the museum during the blitz and often even when there were too few bombs falling to make this respectable. His scientific output was prodigious, including a 350 page monograph on the beetles affecting stored products in addition to a great many solid papers on insect taxonomy and phylogeny.

His work at that time included studies of larval lepidoptera, which led to a general interest in lepidopteran phylogeny. Some of his colleagues at the museum thought that he was devoting too much time to such studies and not to conventional taxonomy. Hinton was therefore glad to move, in 1949, to Bristol University as Reader in Zoology. This gave him greater freedom to choose his fields of study, a choice of which he made good use. He was elected FRS in 1961, to a personal Chair of Entomology in 1964, and became Professor of Zoology and head of the Department in 1970. At Bristol his best known research was his delicate work with the scanning electron microscope, with which he studied and elucidated the functional morphology of many forms of insects and their developmental processes.

Surprisingly for someone not brought up in the English countryside, Howard Hinton was an excellent field naturalist familiar with the flora and fauna of Britain. In fact he said that he derived his inspiration for his apparently esoteric laboratory work from his observations of living creatures in their natural environment. That his interests were not restricted to insects was further demonstrated by his production (with A. M. S. Dunn) of an attractive book on Mongooses.

As well as being an acute observer, a formidable synthesiser and a stimulating teacher, Hinton was an efficient and hardworking editor. He started and brought to success two major scientific periodicals, the *Journal of Insect Physiology* and the *Journal of Insect Biochemistry*. Most scientists would have felt that editing only one such publication was, in itself, a full-time job, yet Hinton managed both without any apparent reduction in his research or other activities. From 1969–70 he was also an effective President of the Royal Entomological Society, and in 1972 of the British Entomological and Natural History Society. Even towards the end of his life, when he knew that he was unlikely to survive until the date of his projected retirement in September 1978, he continued his activities with undiminished vigour and even completed his massive, three volume, monograph on insect eggs. His work in many fields will be appreciated for many years to come.

Kenneth Mellanby

## Leonard Eastham

PROFESSOR L. E. S. Eastham died on 19 July 1977 at the age of 84. Many former students remember him with gratitude and affection, for his understanding of their problems and his effective and unspectacular help. He came originally from Lancashire, and studied agriculture at the Harris Institute, Preston. This course was interrupted by the 1914–18 war, when he served in the Special Brigade of the Royal Engineers. After demobilisation he crossed the Pennines to Leeds, and studied zoology under Professor Walter Garstang. From 1921–27 he was lecturer in zoology at Birmingham University.

In 1927 he was appointed Lecturer in Advanced and Economic Entomology at Cambridge University. At that time Cambridge gave scant recognition to those coming from universities other than Oxford and Trinity College, Dublin (holders of provincial doctorates

were officially 'Mister') and Eastham's position was, at first, not a comfortable or an easy one. I remember him saying that some of his colleagues were so anxious to show their high social status that they forgot to behave like gentlemen. However, he was soon warmly accepted by his students, particularly those taking entomology in Part 2 of the tripos. He proved an inspiring teacher; his knowledge of agriculture, in a department where few had such practical experience, made the subject live, and a number of his students went on to important work in economic entomology in many lands.

From 1932 to 1958 Eastham was Professor of Zoology at Sheffield. Before the 1939–45 war the department was tiny, with only two other academic colleagues. Except for large classes of medical and dental students (1st M.B.) the number of undergraduates was not great, but there were separate classes for intermediate, general degree and special honours students, and a heavy teaching load which would overwhelm most present-day academics. Eastham bore his full share of the teaching, always maintaining his standards. He ran the department efficiently with next to no secretarial help. And he continued actively in research, producing a stream of scholarly and original papers.

After the war, the university, and the zoology department, grew rapidly to many times its previous size. Eastham was Dean of Science, and, from 1946–50, the first Pro-Vice-Chancellor. These and other outside duties did not prevent him from continuing his close and valued contacts with his junior colleagues and his present and past students.

From 1946 until his retirement Eastham played an important part in the creation and development of the new universities being established throughout the British Empire. In 1946 he was a member of a party under Sir William Hamilton Fyfe's chairmanship which visited West Africa and selected the site for the future university of Ibadan. He was a member of the Inter University Council for Higher Education in the Colonies (now for 'Overseas') and its executive, and he paid many visits to the embryonic universities and served on the Council at Ibadan. His visits were always appreciated; unlike many of the 'experts' who were similarly involved he always took the trouble to learn the facts, especially when political and other troubles arose, and his shrewd but sympathetic assessment helped and encouraged those trying to establish institutions of high academic standards under difficult conditions.

24 November 1977

## No jobs left for the boys

A CRISIS is approaching in the employment of scientists in the academic and closely-allied worlds of the UK. Nothing explosive will herald its arrival; there will be no dramatic day on which we shall all wake up to find the newspapers full of it. Rather, over the next few years it is going to be more and more difficult for young people of an academic frame of mind to find a satisfying career. And no-one needs reminding that the influx of young staff is essential to the continued vitality of most academic departments.

The reasons for this crisis have often been discussed in these columns; they stem from three clearly defined factors. First, relatively few people are retiring from university posts at present, or, for that matter, from research-council laboratories or the scientific civil service. The enormous university expansion in the middle 1960s has left the system with large numbers of people now middle-aged: fewer than 1% of all university staff retire this year. The civil service has a somewhat more uniform age distribution, but even so less than 2% retire annually at present.

Second, for the past four years university finances have not allowed vice-chancellors the luxury of filling even such posts as have become vacant without asking the most searching questions about the prudence of taking on a new long-term commitment. The resultant partial freeze on hiring has nudged the student-staff ratio up to around 10:1, or from another point of view has called for an increase in the productivity of university staff.

Third, long term projections of student numbers unambiguously point to smaller universities in the 1990s. For the past ten years the decline in the numbers of those of university age (following the post-war baby boom) has been offset by a steady increase in the percentage of these who seek, and are qualified to receive, higher education. This percentage now seems to have peaked and to be in slight decline whilst the numbers in the relevant age group are rising to a new peak in 1981. For the past ten years then and the next five it seems as if substantial demographic swings will have been moderated by changes in the perceived desirability of going to university, resulting in a slow and controllable expansion in student numbers. But what happens beyond 1981 is anybody's guess. One thing is certain: that by the early 1990s numbers in the relevant age group will be more than a quarter down on those for the early 1980s. So the problem of adjusting university staffing to cope with this demographic change is a severe

one now, and will presumably become even more severe in the late 1980s as those educated at the time of the peak start to look for academic posts.

Thus, to get a job in 1977, you need to find someone who is retiring from a university that is not plagued by financial problems and is confident that in the long-term its student numbers will hold up. Needless to say you will not be the only applicant. And you will find the same competitors pursuing the same limited opportunities in research-council establishments. A supply of suitable people in excess of the demand for them must be one of the factors ensuring that low academic salaries hardly pose a headache to the government, despite mass lobbies and palpable inequities.

How do we get ourselves out of this bind, ensuring that bright minds are not wasted? Clearly some specific initiatives, such as support of more young scientists by the Royal Society, help to take a little of the strain. But it is unlikely that the problem will be seriously alleviated without some radical steps being taken—and in present circumstances these steps can hardly be vast expenditures on new laboratories. If they are we run the danger of acquiring yet another group which grows old together and doesn't start to open up further employment opportunities until the year 2010.

The unspectacular alternative (it can hardly be called a solution) is for very serious examination of the knotty problems of tenure and retirement. In the past ten years scientists, reflecting a national trend, have become ever more cautious of any sort of employment which left them without security above the age of 30, and have then felt safe until the age of 65. The civil service have, of course, led the way in providing a lifetime of stability. There is certainly a lot of good in buffering scientists from short-term change, but is the only alternative a thirty-five year guarantee of employment or, put another way, exclusion for thirty-five years of someone else from the same employment? Surely not when times are becoming progressively harder; some new form of contract of employment must be worked out which can respond to the aspirations of young scientists for employment without humiliating senior colleagues who have given a lifetime of service. Talks are already proceeding on these matters between various interested parties—those involved need every encouragement to come up with some flexible proposals as soon as possible. □

# Will the voice of science of the Third World be heard?

*Michael J. Moravcsik of the Institute of Theoretical Science, University of Oregon, appeals to third world scientists*

MORE than nine tenths of the scientific activity of the world takes place in countries comprising one quarter of the world's population, and most of the Third World at the present is virtually 'out in the cold'. The result is a strong inferiority complex, a necessity of subsisting on scientific and technological 'hand-outs' from the advanced countries, and a society which has not felt the impact of the dynamic world view that the practice of science can engender.

Some of the reasons for this state of affairs are internal to the developing countries themselves, some external. Much of science development must be done by indigenous manpower, with local resources. Other aspects of such a development process hinge on cooperation from the outside since science is a collective undertaking.

It is also a somewhat esoteric undertaking. Its aims, results, and needs do not automatically percolate into society which lacks the background and perspective to initiate interaction with science. Therefore scientists themselves must establish communication with people outside their ranks, and attract support for science making.

In this respect, again with some notable exceptions, the small scientific communities of the developing countries have been quite ineffectual in the past. There are two main groups who should have heard their voice: the policy makers in their own countries, and the world scientific community.

It is rare to encounter a developing country where decisions affecting the provisions for local science are significantly influenced by the active, working scientists of the country, instead of by civil service bureaucrats or by one-time scientists of advanced age who have long lost whatever contact and involvement they might once have had with actual science making. Such 'science policies' therefore are often restricted to the discussion of vague generalities, and in any case deal predominantly with technology and not science.

It is even rarer, however, to encounter a forceful and articulate voice from the Third World speaking out to the worldwide scientific community on behalf of the second class members of this community who happen to live in the developing countries. The large, international magazines used for communication among scientists seldom contain analyses and proposals for reform from representatives of the Third World and the large international conferences very rarely hear from such representatives about ways to make the practice of science more equitable throughout the world. The problem lies outside the consciousness of the overwhelming majority of working scientists.

## Opportunity: a UN Conference

The next two years appear to offer a favourable opportunity to effect a change in this state of affairs. Sometime in 1979 a huge United Nations World Conference on Science and Technology in Development will take place at which it should be possible for science in the Third World to speak out, should it decide to do so.

In particular, national position papers are being prepared, which discuss a country's needs and cooperative capabilities and put forward specific ideas and proposals with respect to any of the four main areas of the conference; science and technology for development, institutions, the United Nations system, and science and technology and the future.

It has been urged that the preparations of these country papers throughout the world be done in full consultation with all interested parties. Yet, it is quite possible that the

preparation of these most important documents in many countries is being done by a small group of people who are perhaps not even involved in scientific activities.

## An appeal

Thus the first appeal I would like to make is that scientists in developing countries make a most strenuous effort to partake in their own countries in the formulation of the country papers. There is no time to be wasted in doing so: the country papers are being written right now, and thus the input must be forthcoming promptly and forcefully. There are perhaps three main relevant areas.

- First, in the area of scientific education. Especially in the initial stages of the scientific development of a country, at least some of the indigenous scientific personnel must be educated abroad, and in this process cooperation from the scientifically advanced countries is an absolute necessity. The problems that arise are not only financial but also centre around the special needs such 'foreign' students have in the context of the education they receive abroad. Proposals have been formulated previously in a profusion of articles and meetings. Action is now needed.

- The second area of concern should be scientific communication. At the present all scientific communication channels are structured so that the scientifically rich get richer, and the scientifically poor poorer. Journal distribution, report and preprint circulation, personal visits, study leaves, conferences, and so on are all designed to yield scientific results tomorrow and hence neglect the yet evolving scientific institutions which promise to produce only the day after tomorrow. This subject has also been fully discussed in the past.

- Finally, and perhaps most importantly, one must create a worldwide atmosphere of opinion in which it is recognised that partaking in the practice of science is a legitimate, nay crucial, ingredient in the overall development process for all countries of the world. The condescending view that doing science is for the rich, and that the developing countries should rather strive to become better fed intellectual and technological slaves to the advanced countries must be changed. Development is a broad concept, and it includes equitability not only in GNP per capita, but also in the self-image of countries with respect to their overall contribution to and standing in humanity. Science development is a very significant element in this.

The second appeal I want to make to scientists in the Third World is to urge them towards articulation through an alternate channel. While much of the formal activity of the conference will be through the process of country papers, the atmosphere of the conference, the stand of individual delegates and speakers, the structuring of the discussion, and in fact even the details of the various country papers from the scientifically more advanced countries can all be significantly influenced by forceful communication through direct channels. Thus it seems that scientists from the Third World should 'campaign' by writing and speaking to fellow scientists the world over, to professional societies and journals, and to the conference organisers, the special office for the conference, headed by Joao F. de Costa, at the United Nations in New York. The more specific and programme-oriented statements and communication are, the more likely they will be assimilated into some action.

In summary, this appears to be the time for scientists of the Third World to rise and let their voice be heard. The psychological circumstances are favourable because of the huge build-up the conference is getting in political terms. The channels are also available. All we need now is action. □

# Combatting rickets

Researchers, nutritionists and policy-makers face a problem over rickets in Britain, as **Alastair Hay** explains

A QUICK survey of the British public would suggest that its nutritional problems are not due to a lack of food. Yet even in the midst of overconsumption a specific nutritional deficiency—that of vitamin D—has been defined in certain sections of the population. Rickets, known to generations of Europeans as the 'English disease' is now a problem in the children of Britain's Asian community and occurs sporadically in some of the infants of the country's poorest populations. It was first reported as being a serious problem in the Asian children of Glasgow almost sixteen years ago and has since been observed in one Asian community after another throughout the country.

The summer issue of *Science for People*—the publication of the British Society for Social Responsibility in Science (BSSRS)—asserts that the UK Department of Health and Social Security (DHSS) actually causes rickets. The journal is noted for a blunt approach to the issues it tackles, but this attack will not be viewed altogether unfavourably by many clinicians concerned with the health of Britain's Asian population and particularly with the problem of rickets. They point out that the problem is well known—perhaps too well known—and that there has been no shortage of surveys and quotable figures. They claim that most of the answers to this proven dietary deficiency are known, but that the DHSS has so far failed to adopt a positive approach.

Faced with such hostility the DHSS has been giving the matter serious attention. The department's Committee on Medical Aspects of Food Policy (COMA) is reviewing the whole question of bone disease contracted as a result of nutritional deficiency. The committee's deliberations have been somewhat protracted and are still by no means completed. But a report is expected that will produce some recommendations for action.

It is children who suffer from rickets; the same bone disorder in adults is termed osteomalacia. It results from an inadequate supply of vitamin D. The vitamin is required for the active absorption of calcium and phosphorus from the gut. When this mineral supply is reduced in vitamin D deficiency, the body, in order to maintain blood mineral levels, has recourse to its only other source of supply, the bones. Bone growth ceases, the skeletal structure become progressively weaker

and eventually deteriorates to produce 'bow-leg' or 'knock-knee' rickets.

Although biochemists are having a field day trying to elucidate vitamin D's exact mode of action, at the nutritional level the problem would seem to be simply that of ensuring an adequate supply. But the solution is not as easy as it seems, which could be one explanation why the DHSS is taking so long to formulate a policy. The question that needs answering concerns the most effective vehicle for administering the vitamin: should it be done through chapati flour, or milk, or vitamin D capsules, or tablets?

As a major constituent of the diet

of most Asian families, chapati flour would seem to be an ideal medium through which to add extra vitamin D to the diet. The technical problems of mixing the vitamin and of its preservation have been solved, and clinical trials using vitamin D-fortified chapati flour have shown its effectiveness as a method of administering the vitamin. A problem may arise with regard to the concentration gradient. It is children, not adults, who are most in need of extra vitamin D, and adults consume more flour per head. The answer would be to have two types of flour, one fortified and recommended for children, the other unfortified. But as a spokesman for a bread company says: "Someone has to pay for the process".

Milk poses different problems. There are no legal constraints to forbid fortifying chapati or brown flour with nutrients; this is not true of milk. Britain is bound by an EEC directive forbidding any alteration to the composition of milk. When the issue was discussed in Brussels, several European countries were in favour of legislating for a 3½% fat level. Britain fought this, primarily on financial grounds, and insisted on the right to have milk virtually unaltered from cow to con-

sumer (most milk would have to have fat removed to attain the 3½% figure). The British case was conceded, but at the time Asian rickets was not considered to be a problem; now it is. Before embarking on any milk fortification programme Britain would first have to return to the negotiating table, which could be embarrassing, but little choice may remain if the DHSS comes out in favour of using vitamin D-fortified milk. The arguments in favour of its use are strong. As children drink more milk than adults, it would reach the population most in need of treatment. Those in favour of milk point out that Canada fortifies milk, milk products and margarine with vitamin D; the United States does the same and much else besides.

As for the third suggestion that vitamin D capsules or tablets be dispensed either at clinics or in schools, staff in some schools are opposed on the grounds that the procedure of identifying children in need from the school register is too complicated.

As breast-fed babies in Britain rarely develop rickets any health education policy ought to discuss the merits of breast feeding as well. The reason for this immunity is not yet clear, but is probably related to the fact that the breast milk of vitamin D-replete mothers contains a fairly high concentration of the vitamin present as vitamin D sulphate. Some groups of immigrant women stop breast feeding when they arrive in the country and resort to doorstep milk.

## No significant impact

It is generally acknowledged that the health education programmes dealing with rickets have failed to make a significant impact in the Asian community. Some clinicians argue that these programmes have failed dismally in alerting local doctors and health workers to the seriousness of the problem. They add that there is great inertia at the level of the community physician, that many doctors are reluctant to become involved in preventative campaigns, and that many health workers have not been informed that the problem exists.

That rickets is present in the Asian community, and a serious problem, is not in doubt. Some may query the figures for the prevalence of the disease, and argue for more information. Others will say the evidence is now so overwhelming that action must be taken. The DHSS recognises that many doctors expect its COMA committee to make some positive recommendations stressing the need for a food fortification programme backed up by a good health education policy reaching all the Asian community. □

## More cash for British science

THE UK Advisory Board for the Research Councils (ABRC) is considering how to divide the second windfall to have landed in its lap this month amongst the five research councils. In reply to a question in the House of Commons late last week Shirley Williams, Secretary of State for Education and Science, announced an extra £4 million for the science budget which is to be spent on "new capital work" in 1978-79. It is in addition to the £4 million allocated to the research councils in the mini budget at the beginning of the month.

The new £4 million is to come out of the £400 million allocated to the construction industry in the mini budget. It is strictly for building and, because of its small size, is more likely to be used for improving or extending existing facilities than starting up new ones.

Professor Geoffrey Allen, Chairman of the Science Research Council, which is almost certain to get the lion's share, would like to see the money going towards finishing construction already begun and extending central user facilities. He feels that this might be an opportunity to complete the nuclear structure facility at the Daresbury Laboratory and extend facilities for the synchrotron source there. The laser facility and spallation neutron source at the Rutherford Laboratory might also come in for a share of the cash.

Another priority in the SRC is likely to be helping universities provide facilities for marine technology and polymer engineering. These are research areas considered to be of national importance and currently receiving special treatment from the SRC. The

only new project which might be considered is an electron beam lithography unit for microelectronics which could be set up in existing buildings at the Rutherford.

The cost of implementing these projects alone could come to £3 million. When the cost of the bids for support from all the research councils is added up, it will undoubtedly be much more than £4 million, so the ABRC is in for a difficult task. Nevertheless, it hopes to have made the necessary decisions by the end of next week or at the latest by its next formal meeting which is set for 9 December. A decision on the earlier £4 million, however, is unlikely to be made public before the end of the year although it has been made and is awaiting Mrs Williams' approval. It will probably simply be added on to the total science vote for 1978-79 which will be announced sometime in the new year.

## Leading Soviet dissidents in London

DURING the last month, three leading figures from the Soviet dissidence and human rights movement have visited London. According to the most recent arrival, Dr Khronid Lyubarskii, an astrophysicist, their presence in the West reflects a determined effort on the part of the Soviet authorities to overthrow all opposition, neutralising the leaders by removing them from the scene. Neither Dr Lyubarskii nor Dr Valentin Turchin, the cyberneticist, who were expelled together on 14 October, had any real desire to leave the Soviet Union. They had applied for emigration only when the authorities had made it clear that they must choose between foreign exile or a protracted stay in a labour camp. The third visitor, Professor Mark Azbel, a theoretical physicist, had indeed had a genuine wish to leave the Soviet Union, having applied several years ago for a visa for Israel. After several years as a *refusnik*, Azbel finally received his visa last June.

It is no coincidence that all three are scientists. The dissident movement has a strong bias towards the scientific professions, since, in Dr Lyubarskii's words, "a scientist works in information—it is therefore natural that he begins to think about the society around him. It is the critical mind of scientists that leads them to think of human rights".

Their record of service to the human rights movement is impressive. As early as 1970 Turchin, together with Roy Medvedev, signed the second Sakharov letter. In 1972, Lyubarskii

was sentenced to five years in a strict-regime Labour camp for his human rights activities, and while there organised the observance of an annual Political Prisoners' Day (30 October), to be marked with protests and hunger strikes. For this further transgression, Lyubarskii was transferred to the Vladimir prison for the duration of his term. Both Turchin and Lyubarskii became members of the illicit Moscow group of Amnesty International, and were associated with the Helsinki monitoring group.

On the arrest of Aleksandr Ginsburg last April, Lyubarskii took over the administration of the Solzhenitsyn fund for aid to political prisoners. Unlike many Jewish activists, Dr Azbel feels it better to keep the Jewish emigration movement separate from the dissident movement for reform and human rights. This is not a distinction, however, which the Soviet authorities accept—application for emigration is an antisocial act, just as much as signing a petition of protest, and is punished in the same way by dismissal from one's job, with no possibility of continuing one's professional career.

Dr Lyubarskii gave an interesting estimate of the numbers of scientists penalised for their activities:

involuntary foreign exile	a few
arrests	tens
expelled from jobs	hundreds
routine restrictions after	thousands
signing protests etc (refusal of foreign passport, administrative restrictions).	

It should be remembered that punitive dismissal is far more serious a penalty than loss of job. In the Soviet Union no academic article can appear without a certificate from the academic institution where the author is employed. No 'freelance' submissions are permitted. "If Einstein or Faraday had lived in the Soviet Union, they could never have published their theories" stressed Azbel.

How well a scientist can survive professionally under such conditions seems to depend very largely on his particular field. In spite of several years without employment or professional facilities both Turchin and Azbel have found themselves able to continue their professional careers in the USA and Israel respectively. For Dr Lyubarskii, however, the outlook is bleak. His special field, the physics of planets, meteors and meteorites has moved forwards at such a pace that he feels doubtful whether he will ever catch up after almost six years with no access to journals.

Whatever their new professional commitments, all three are firmly committed to campaign for fellow-scientists still suffering constraint and imprisonment, and, indeed, they came to England for this purpose. They will campaign for physicist Yurii Orlov—now in prison; biologist Sergei Kovalev—in a labour camp; mathematician Viktor Brailovskii, Azbel's successor as leader of the Sunday seminar, who is threatened with a treason charge; and the young mathematician Anatolii Shcharanskii whose trial on treason charges now appears to be imminent.

## Soviets honour teamwork and technology

It is sixty years after the revolution—but the 1977 Soviet State Prizes for Science and Technology show no sign of anniversary euphoria. The works cited seem genuinely to reflect the current state of progress, without any attempt to honour 'great names' on this special occasion. There is considerable emphasis on teamwork: the majority of citations involve long lists of project-directors, assistants, and technicians, so that the announcement of 38 awards with the names, academic or professional titles, and affiliations of the recipients fills a page of *Pravda*.

The citations span the usual wide range from mathematics to biology, with occasional incursions into fields not normally considered sciences in the West—Marxism and its ancillaries of history and economics. Current Soviet doctrine, as expounded at recent Party Congresses, demands that science should serve the national economy. Accordingly, several prizes go to research directly related to official priorities—a set of geological maps of Western Siberia, special equipment for land reclamation, fisheries equipment, and the use of discrete transformations in automatic control. The recent voyage of the icebreaker *Arktika* to the North Pole won a State Prize for her designers and engineers (though not for the scientific team aboard).

The medical sciences, which have recently received a new priority including the establishment of the title of merit "People's Doctor of the USSR", are well represented. Three science prizes go to long-term medical research: two—for haematology and prophylactic helminthology—mention "cycles of works" published over the last 15 years, while the third—one of the very few individual awards—cites a haematological monograph which also implies a long-term basis of research. Medicine also receives two technology prizes, where the citations seem rather more adventurous—new equipment for hyperbaric oxidation, and the "clinical development and implementation" of methods of limb transplantation.

In a year of setbacks for the space programme, it is not surprising to find space ignored in the technology section, although it does receive one science award—for research into the X-ray emission of the sun.

Nuclear research receives only one

award—for research into the hard X-ray fission of light nuclei. Commenting on this prize, the Chairman of the State Prize Committee, Minister of Higher and Secondary Specialised Education, Vyacheslav P. Elyutin, stated that "this work is of exceptional significance for the study of thermonuclear reactions and radioactive fallout". Nevertheless, in view of the repeated acclaim given in the Soviet media this last year to the fast-breeder power programme, it is a little surprising that there is no technology prize for nuclear engineering. The only other mention of nuclear physics is in the "textbook" section—for a two-volume university text on experimental nuclear physics.

This separate section for textbooks is a relatively recent innovation. In the Soviet Union, textbooks are selected by the educational authorities on a Union-wide basis, so that, on occasion, criticism of an unsatisfactory text will lead to a discussion in top-level party journals. The demand for scientific personnel is expanding with each Five Year Plan—the current Plan requires an "output" from the universities and institutes of higher education of 9.6 million new scientists, technologists and specialists in the period 1976 to 1980, so the provision of suitable textbooks is a matter of ever-increasing importance. This year two other university textbooks, on pedology and invertebrate palaeontology, are also honoured, as is a secondary school text on economic geography.

## Recombinant DNA

THE final Environmental Impact Statement (EIS) on the NIH guidelines for research involving recombinant DNA molecules was published last week, more than 16 months after the release of the guidelines themselves. The formulation of the final EIS has been fraught with delays and uncertainties. An initial draft which came in for some heavy criticism was published over a year ago along with an invitation for informed comment. Drafting an acceptable final version has taken much longer than expected, and the publication schedule has slipped several times. This delay may have legal consequences. Friends of the Earth has filed a suit against the NIH and NSE in an attempt to halt funding of recombinant DNA research, charging breach of the National Environment Protection Act on the grounds that the EIS was not published simultaneously with the guidelines. The NIH counter this by pointing out that delaying publication of the guidelines would have led to greater delays in applying adequate safeguards to the research.

As for the EIS itself, there are few surprises. The document and its extensive appendices go over all the familiar arguments concerning the potential and postulated environmental impacts of recombinant DNA research and comes to the unsurprising conclusion that "the level of risk that will result . . . is acceptably small." This conclusion and the arguments used to support it will undoubtedly supply ammunition to both sides of the continuing debate.

Sandy Grimwade

Above: the Meridian Room at the Dunsink Observatory of the Dublin Institute for Advanced Studies, where a major fire early last October severely damaged the library and laboratories. Loss of instruments has meant loss of valuable work. But Professor P. A. Wayman, Director of the Observatory, is hopeful that the observatory will be restored. He sees as first priority getting the smoke damaged computer back into action. Restoration of the eighteenth century building which housed the library is likely, though not definite yet.

The Observatory was founded in 1783 and became part of Dublin University. In 1947 it was taken over by the Dublin Institute. It has no telescopes of its own.

Chris Sherwell, News Editor of Nature for the past two years, has taken up a post on the foreign desk at the Financial Times. Robert Walgate, until recently with New Scientist, takes Mr Sherwell's place. And David Dickson, recently with the Times Higher Educational Supplement, becomes our Washington News Editor at the beginning of 1978.

## Austrian science minister attacks science journalists in fraud case

THE Austrian Minister for science and research, Dr Hertha Firnberg, released a 32-page document last Wednesday (16 November) attacking the science journalists of Austrian and other newspapers for poor judgment, and for unwittingly assisting in the execution of a crime. The attack, whether justified or not, threatens to disrupt the relationship—already fragile—between Austrian journalists, the ministry and the scientific community.

The government statement singled out two journalists for particularly harsh treatment: Dr Eleonore Thun-Hohenstein of the conservative daily *Wochenpresse* and Paul Uccisic of the middle-of-the-road *Kurier*. Their error? Publicising the work of a little-known freelance microbiologist, Herbert Schaden, and his assistant Hertha Celta. Schaden and Celta claimed that they had developed, or would soon develop, a strain of microbe which would digest plastic. No such strain emerged after four years' work.

Schaden was detained in Austria on 11 January, and has been in jail since, awaiting trial on charges of fraudulently obtaining funds for research (amounting to some £½ million) from a Dutch packaging firm and other sources. Celta was imprisoned with him but released on bail after two months—to feed Schaden's microbes. The microbes and Celta languish yet in Schaden's private laboratory at 99 Panzingerstrasse, a fashionable turn-of-the-century Viennese villa.

Dr Firnberg's document implies that Schaden is a crook—albeit a very clever one—and attacks the journalists for helping him along the path to fraud. Some 750 articles describing Schaden's work appeared in the press between 1 February 1973 and 5 June 1974, the document states, mostly in Austria, but also in Holland and in Italy.

Schaden first came to the journalists' attention on 1 February 1973, when he sent a thick bunch of documents to the Austrian *Bundersministerium für Wissenschaft und Forschung*, with copies to the Austrian newspapers. The documents gave credentials, references, and evidence that Schaden and Celta had found the plastic-digesting bug. Years before, a stack of plastic containers had been found riddled with microscopic holes; Schaden had deduced the presence of bacterial action and set about isolating the active agents.

On 21 February 1973 Thun-Hohenstein's first article, a positive one, appeared in *Wochenpresse*. A Dutch journalist noticed the story and

relayed it to her paper, the *Haarlems Dagblad*, a small but important provincial Dutch paper.

Oscar van Leer, a Dutch packaging magnate, came to hear of the story and was interested. Uccisic published his version of Schaden's work, also positive, in *Kurier* on 4 March. By 30 May Thun-Hohenstein had heard both that the Austrian ministry had dismissed Schaden ambiguously with a "don't ring us, we'll ring you", and that van Leer's firm (Royal Packaging Industries van Leer B. V.) was investing in Schaden's bugs. van Leer had sent a team of plastics experts—but not microbiologists—to interview Schaden and concluded he was genuine. Thun published a sarcastic article ridiculing the ministry's delay and poor judgment. On 9 June Uccisic, not a man to mince words, weighed in with his own criticism. He printed a story related by Thun: that the chief civil servant responsible for advising on the allocation of research funds in Austria—Dr Wilhelm Grimburg—had threatened Thun with a court action for saying the ministry's rejection of Schaden took five lines rather than the five and a half. Uccisic made great play of that. Later a letter from Grimburg was printed in *Kurier* rebutting Uccisic's accusations; but Uccisic tacked a stinging comment on the end.

Grimburg's relationship with Thun-Hohenstein and Uccisic was therefore very sour; the more so because the ministry's popularity with scientists was at a low ebb. Austria was—and is still—enjoying its first period of socialist government for a long while, and the ministry had embarked on a "demo-

cratisation" of the universities (for which it is responsible), introducing students and junior professors on to decision-making bodies, and dismantling the previous patriarchal and authoritarian structures. Criticisms of competence were particularly unwelcome at that time.

But now has come the retribution. van Leer invested a large sum in Schaden, only to find his work and his claim valueless. van Leer's lawyers believe they have discovered that some 40 pages of Schaden's original documentation are careful re-writes of earlier German papers, changing names and places. So the ministry appears to be vindicated (though Schaden and Celta's case has yet to come to court, and some feel that due process of law has been disturbed by the ministry's attack). Dr Firnberg, the minister, threatens wide distribution of the report, to all politicians and universities in Austria, an act which will undoubtedly severely weaken the position of the science journalists within their own newspapers and in Austria itself.

What of the journalists? Dr Thun-Hohenstein dismisses the Firnberg attack and indeed still believes in Schaden; Herr Uccisic thinks Schaden "not the person we took him for". He feels however that "neither I nor Dr Thun-Hohenstein nor anyone has any proof" that Schaden is wrong. And many journalists are saying that as it has taken experts since 11 January this year to develop a watertight case against Schaden—and may take longer—how can they have been expected to judge? The development was potentially of great public interest so had the public not the right to know?

Uccisic also takes a more philosophical view. "Error is always possible" he says; "even politicians and scientists can make errors". Uccisic believes scientific officialdom to be too hidebound—which it sometimes is—and he takes an interest in fringe science. But the belief can lead one into dangerous territory. Uccisic recognises the danger but adds "We should be open-minded and ready for new developments. In this special case no law of science forbids the development of organisms that might digest plastic. And Schaden was employing a recognised technique: to isolate a useful strain and strengthen it by multiplication and selection".

The final criticism must be laid at the door of the ministry itself. The ministry accuses the journalists of superficiality and lack of thoroughness. But the document they have produced in their haste to attack the journalists suffers from the same fault. It is too polemical; and its puts only one side of a difficult case.

Robert Walgate

Herbert Schaden and Hertha Celta, accused of obtaining £½ million by false pretences

## EEC taps a megawatt of Italian sunshine

THE EEC Commission and a consortium of European companies signed a construction contract in Brussels last week for a £3 million electricity generating plant operated by the sun. The plant will probably be built in the south of Italy, and should be producing a megawatt of electricity by 1981—enough power for between 100 and 200 households.

Two hundred and fifty mirrors, covering a hectare of ground, will be used to reflect and concentrate the sun's heat on to a boiler, on top of a 50-metre-high tower, to produce steam to drive conventional turbines. The heat receiver will be about four metres square. Each square metre of mirror will generate 1 kW. The plant will have a thermal power of about 5 MW indicating a thermal efficiency of 20%. It will operate with steam at 510 °C and

64 atmospheres. The mirrors will be computer controlled to follow the sun and the whole structure will be solid enough to withstand winds of up to 130 km h<sup>-1</sup>.

This will not be the first such solar electricity generating plant. France, which is taking part in the project, already has its own 2 MW plant near Marseilles and Macdonnel Douglas in the USA is planning to build a 10 MW plant in California at an estimated cost of \$31 million. But because of spending cuts that is likely to be delayed.

All these plants, however, will be expensive, experimental projects, operating on an uneconomically small scale. The maximum possible output for a solar plant is thought to be about 100 MW. Beyond that it becomes physically impossible to get more mirrors close enough to the boilers to

have any effect. Major modern electricity generating stations can produce 1,000 MW, and Mr Albert Strub, head of the EEC Commission's non-nuclear energy department, estimates that "if 5% of Europe's energy comes from the sun by the year 2000, we will be doing well".

The aim of the Italian plant is to teach the companies concerned the technical problems involved. The firms concerned are: the Italian national electricity company, ENEL; Ansaldo of Italy; Cethel (grouping the French companies Renault, St Gobain and Heurtey); and Messerschmitt-Bolkow-Blohm of West Germany. General Technology Systems of London will advise the Commission on the management of the project. Half the cost will be met from the Commission's research budget, the remainder coming from the participating countries.

Brian Donaghy

THE Royal Society of Tropical Medicine and Hygiene is holding a symposium this year, from 23 to 25 November, to celebrate the first centenary of medical entomology. It is just one hundred years since Patrick Manson showed that *Culex fatigans*, the common house mosquito of the tropics, was the intermediate host of a nematode worm which caused the disease filariasis in man. That was the first time an insect had been so involved, and although other scientists were engaged in parallel investigations, and there have been unpleasant confrontations between those supporting other claimants to priority, I have no doubt that Manson fully deserves this accolade.

The novelty of his discovery is manifest when we examine the records of his time. The more traditional members of the medical profession called him a lunatic, and intended to ridicule him when they gave him the nickname 'Mosquito Manson'. However, he inspired a few of his colleagues, particularly Ronald Ross. To the general public Ross, the discoverer of the transmission of malaria by the mosquito, was the more popular figure, but Ross himself always acknowledged his debt to Manson.

I do not think that it is any exaggeration to say that Manson's work has had a more profound effect on the human race than any other discovery which can be attributed to an identifiable individual. We cannot name the benefactors who discovered the wheel, the use of fire and the possibility of growing arable crops: their contributions may have been more revolutionary to man's way of

life, but the results are of the same order of magnitude. But for the work of Manson and those he inspired, the populations of many tropical countries might today be less than half their present level.

### Mosquito Manson

KENNETH MELLANBY

A hundred years ago the majority of the world's population lived in areas where diseases which we now know to be transmitted by insects (and in no other way) dominated the lives, and the deaths, of the inhabitants, yet no one had the faintest idea how the diseases might be controlled. Even today malaria, typhus, sleeping sickness, filariasis, dengue and many more diseases are still important, claiming many victims and affecting all types of development, but we know how they could be reduced or even

eradicated. Though patchy, some degree of control has been widely implemented. The resulting rise in population may not be an unmixed blessing in a world of shrinking resources, but to many individuals, particularly in tropical countries, the improvement has been dramatic.

Although a hundred years ago no one appeared to believe that insects could carry diseases, it is tempting to search for earlier suggestions of such a mechanism. It is true that authoritative books on the English fens produced in the nineteenth century which devote much space to "the ague", which was generally malaria, give no inkling of any idea other than that the disease was caused by the "bad air" from the marshes. They discuss the importance or otherwise of water pollution by organic matter, which can now be interpreted as affecting the survival of mosquito larvae, but there is no mention of mosquito bites as a danger to health. However, I recently found a contemporary account giving an inventory of the contents of the Cistercian Abbey at Sawtry, only a couple of miles from where I write in Huntingdonshire, at the time of the dissolution of the monasteries in the sixteenth century. The Abbot's chamber had a feather bed and white curtains, but the guest room, reserved for important visitors, was hung with tapestry and a bedstead with "nets for knats". This may have been to protect the guests from infection with malaria, but I fear that it was just for his comfort and to keep out the insects which can still be troublesome on warm summer nights in fenland. But it may have kept him healthy all the same.

# correspondence

## Farm energy

SIR,—I am not sure what your correspondent Michael Knee is trying to say in his letter (13 October, page 556). He accuses me of "blind prejudice" for stating a few simple facts about the use of energy by farmers. If he reads my contributions in the issues of 25 August (Frugal farming) and of 8 September (Food for energy), he will find that he has misinterpreted my views.

I would be the last to deny that an enormous amount of energy is wasted by some modern farmers, but this is almost entirely because of the inefficiency of intensively-kept livestock, which waste over 90% of their food, and which is the main reason why Britain is not already largely self-sufficient. This is mentioned in my contribution of 25 August, and explained in detail in my book *Can Britain Feed Itself*. But this is irrelevant to the present argument.

My contention is that arable farming is efficient. It has been shown by everyone who has investigated the situation, including Gerald Leach in his *Energy and food production* (mentioned by Michael Knee) that arable farming, although using much energy to propel tractors and manufacture fertilisers, produces crops with at least three times the energy value of that used in growing them. Recent developments, such as direct drilling, will reduce energy expenditure without reducing the yields, and so further improve the equation. In fact intensive arable farming is probably the most efficient way we can trap solar energy in an easily useable form.

Like Michael Knee, I would like to see more people working on our farms, but men, like horses, would probably use more energy in a twelve-month than the present tractors and combine harvesters, if we were to grow and harvest comparable crops.

Yours faithfully,

KENNETH MELLANBY

Huntingdon, UK

## Desert rainfall

SIR,—The statement by Glantz and Katz (19 May, page 192) with regard to measuring rainfall at two locations, Gao and Niamey, in the Sahel "that at least is some sense, the mean is too large and not at all indicative of how much rain commonly falls" is overly

strong. In no sense is the mean too large; the mean is simply the mean—a well defined and much used statistic. Furthermore it is quite indicative of how much rain commonly falls in most regions—even Gao and Niamey. Glantz and Katz also note that positive "skewness is characteristic of the rainfall distribution not only in the Sahel but, more generally, in arid and semi-arid regions. In particular the degree of skewness is greater the drier the climate". It has been our experience, however, that positive skewness is a characteristic of rainfall distribution for almost all localities and that, at most, there seems to be only a slight tendency for the degree of skewness to increase as the average amount of precipitation decreases.

We selected a random sample of fifteen reporting localities from the original *Climatic Summary of the United States* which contained data from the establishment of reporting stations up to 1930. The only restrictive requirement imposed in the selection process was that there had to be at least twenty consecutive years of records for a given locality. We used the mean, standard deviation, and coefficient of skewness for the distribution of precipitation at each location to examine the hypothesis that the more arid the climate the more skewed the distribution rainfall. If the hypothesis is valid, there should be a strong negative correlation between mean rainfall and the skewness coefficient. We found that there did seem to be more skewness for regions with little rainfall in the month of July than for a region of average rainfall, but positive skewness also seemed to be greater for regions with greater than normal rainfall. The correlation coefficient of  $r = -.08$  tends to confirm the lack of a simple systematic negative relationship between mean rainfall and skewness.

It also should be noted that positive skewness seems to be the normal condition for the distribution of rainfall for almost all localities and not just for the localities in arid regions. The meaning of this should be evident. If it is not true that the mean alone is suitable for describing the distribution of rainfall in arid regions, then neither is it alone a suitable measurement for describing the distribution in any region. This, however, is not a surprising result; few distributions can be de-

scribed by one parameter. As Glantz and Katz state, "no single number can adequately describe the climate regime of an arid or semiarid region". We would add that the statement holds for all regions and not merely for arid or semiarid regions.

We also would like to add a note of disagreement with the statement that, "recent weather tends to influence perceptions more heavily than earlier weather and wet spells more heavily than dry ones". While the statement about recent weather versus earlier weather seems totally acceptable, the latter part of the statement would seem to need at least some documentation. What evidence exists to substantiate this statement? If nothing else, it does seem evident that the drought of the past few years in the Sahel will influence perceptions and behaviour quite as much as the earlier wet spells.

Yours faithfully,

J. LARRY DEATON

United States Department of  
Agriculture,  
Washington DC

## Using varied talents

SIR,—I was unpleasantly surprised at your negative editorial comment on Sir Andrew Huxley's Presidential Address (8 September, page 95). Accepting the idea that inherited differences exist does not automatically condemn the apparently less-endowed people to a subhuman status. Those with no apparent talent are not necessarily inferior; they simply can't find their true calling in our culture. A century ago born atomic physicists and computer programmers may have spent their lives on the skid row as impractical silly dreamers; today they are productive, well-regarded members of our society.

As civilisation advances, more and more people will find the calling that uses their innate talents; fewer and fewer will spend their lives as frustrated misfits. All we have to do is to maintain progress in our civilisation, so more and more varied talents can be used. However, to maintain this progress we must have the courage to face the apparently impalatable as well as the palatable results.

Yours faithfully,

ANDREJS BAIDINS

Du Pont Company,  
Wilmington, Delaware,  
USA

## DNA insertions and gene structure

from Bob Williamson

ONCE again we are surprised, this time by the structure of genes coding for proteins in higher animals. The primary sequence of the protein is determined by messenger RNA (mRNA); this in turn is synthesised on one of the strands of genomic DNA, probably first as a precursor of high molecular weight (HnRNA). Several animal cell mRNAs have been sequenced in whole or part, revealing no peculiarities so far: the coding sequence is preceded by a capped, non-translated region, starts with an initiator triplet, and is read in phase to the 3'-terminator triplet, which is followed by a non-translated 3' region and last, a polyadenylic acid sequence. The sequence of the coding region of the mRNA exactly specifies the amino acid sequence of the protein when read in register.

It was assumed that the mRNA was copied directly from a gene sequence, and data from prokaryotes certainly supported this view—a frame-shift mutation in which a base was added or deleted caused the predicted change in protein sequence, and even, in an operon, in proteins coded adjacent to the 3' side of the genome. In animal cells, however, this now turns out not to be the case, at least for ovalbumin and  $\beta$ -globin genes.

These genes are particularly suitable for study as they are present only in single copies, and tissues which make each protein in large amounts can be compared with those that make little or none. The specific mRNAs are available, and the construction of recombinant DNA plasmids has removed the problems of purity and amount that particularly apply to single-copy genes because they are present in the sequences in nuclear ('genomic') DNA only as one part in several million.

No sooner was an appropriate recombinant clone of DNA available (courtesy of T. Maniatis) than Flavell and Jeffreys started the analysis of the genes for rabbit  $\beta$  globin. They 'mapped' the gene—that is they found the size of the DNA fragments containing the gene when the DNA was digested with various restriction enzymes by techniques developed by Southern (*J. molec. Biol.* **98**, 503; 1975). They looked for the nearest repeated DNA sequences, the nearest short poly(dA) runs, and so on. It all made sense for a while—the gene for  $\beta$  globin (there are actually two related genes, which seem to correspond to the  $\beta$ - and  $\delta$ -globin genes in humans) at first behaved correctly, and a picture of the gene itself, the surrounding bits of DNA and the minimum distances to other genes became partially clear (Jeffreys & Flavell, *Cell*, **12**, 429–441; 1977).

Then more enzymes were used. When a variety of enzymes is used, in a way analogous to that in which proteases are used to determine protein sequences, they have to 'add up'—if sequence AC is cut at point B, then AB plus BC has to equal AC. This is so 'self-evident' that Jeffreys and Flavell deserve the greatest praise for not dismissing their data out of hand when they showed that 2+2 does not always equal our preconception of 4.

In the  $\beta$ -globin mRNA, the sequence of bases starts at one end with the triplet specifying the N-terminal amino acid of the protein and moves steadily and without interruption to the other end, where the protein terminates. But in the gene the sequence of bases coding for  $\beta$  globin is not continuous. In particular one fragment of cloned complementary DNA (obtained by reverse transcription of the mRNA) which is 333 bases long, derived entirely from the coding sequence and bounded by two *Hae*III restriction sites, hybridises to a *Hae*III restriction fragment of genomic DNA that is more than twice

as big. Clearly the restriction fragment contains an additional insert (some 700 base pairs long). The only conclusion must be that there is a bit of DNA, as big as the structural gene for  $\beta$  globin itself, in the middle of the gene, which does not appear in the final mRNA (Jeffreys & Flavell *Cell*, in the press).

At the same time as Flavell and Jeffreys were obtaining this startling result, Leder *et al.* were recording a related and equally inexplicable finding (*Cold Spring Harb. Symp. quant. Biol.*, in the press). Leder's group had first to prepare a safe vector to clone mammalian genes, and chose bacteriophage  $\lambda$ . They introduced a number of mutations and deletions so that only recombinants could be 'packaged' and so reproduce, and also several mutations which rendered the phage non-viable outside controlled laboratory conditions. They then purified the gene for mouse  $\beta$  globin several hundred times using a combination of reverse phase chromatography (which separates on base composition and secondary structure) and Agarose gel electrophoresis, and obtained two fragments approximately 15,000 and 7,000 base pairs (15 kb and 7 kb) long. Each of these, while much purified over the original DNA, still only contain one globin gene-containing sequence in every thousand or so total sequences.

The mixture was then recombined with the disabled  $\lambda$  vector. Recombinants containing the mouse  $\beta$ -globin gene were selected. The length of the cloned mouse DNA was ten times the size of the coding sequence, some 7 kb long, and contained the entire  $\beta$ -globin gene. However, once again, it was not all in a single piece, for when it was hybridised to mouse globin mRNA and examined with the electron microscope, a remarkable extra loop in the middle of the DNA was found. Restriction enzyme analysis confirmed the existence of the insert. This insert is 450 base pairs long—it is not yet clear whether it is in the same position as

for the rabbit insert described by Flavell and Jeffreys, nor whether its sequence is conserved.

The chicken ovalbumin gene has been studied almost as extensively as the globin gene, largely because it is hoped to learn from it more about gene action in response to hormone stimulation. Because it is present only in a single copy, fragments of genomic DNA prepared using a specific restriction endonuclease which does not break the gene should once again give a single DNA fragment containing the gene—if the sequence is present as a single unit in the DNA as in the mRNA. However, two groups have just shown that as for globin, several fragments rather than one are often found (Breathnach, Mandel & Chambon, this issue of *Nature*, page 314; Doel, Houghton, Cook & Carey, *Nucleic Acids Res.* **4**, 3701–3713; 1977).

Chambon and his colleagues first prepared a recombinant plasmid between complementary DNA (cDNA) prepared from chick oviduct ovalbumin mRNA and pCRI. This enabled the Strasbourg group to determine which restriction endonucleases did not cleave the coding regions of the gene.

A slightly different approach was used by Carey's group at Searle. They first prepared very pure mRNA and isolated full length cDNA, and then synthesised a second complementary strand with reverse transcriptase. Full length double strand cDNA was isolated by Agarose gel electrophoresis. This too could be checked for restriction enzyme sites in the coding gene region. (Carey *et al.* also checked their results against the plasmid prepared by the Strasbourg group, a good example of international co-operation in the use of recombinant DNA.)

Neither of the restriction enzymes *EcoRI* nor *HindIII* cleaved the structural gene sequence in Chambon's plasmid or Carey's double-stranded cDNA. These then were the enzymes used to fragment genomic DNA from chick tissues.

Both groups, using their different techniques, found three DNA sequences which hybridised to either cDNA or nick-translated plasmid DNA after restriction of genomic DNA with *HindIII*. Using *EcoRI*, Chambon *et al.* found convincing hybridisation in four positions. Thus instead of a single band expected, several gene-containing regions separated by long inserts, or spacers, are found. Moreover, this is true for all tissues studied, whether making ovalbumin or not.

In the case of mouse and rabbit  $\beta$  globin, the entire coding gene was isolated, with the insert in the middle. The structural gene regions were therefore at least closely linked, if separated by the unexplained sequence. In the case of ovalbumin, however, no frag-

ment containing both coding sequences has been found and one of the inserts is at least 7,000 base pairs long. It is even theoretically possible that different regions of the ovalbumin structural gene are on different chromosomes, and not linked at all.

How can this remarkable result help in the understanding of transcription? Very little, until several questions have been answered. As Chambon *et al.* point out today, there are three apparent possibilities. The 'primary' transcript (the HnRNA containing the mRNA sequences) may include the inserts and all the mRNA coding regions, with the inserts being specifically nicked out and the mRNA ligated to its final form in processing. This is quite possible because, as has been stated here (*News and Views* **269**, 648; 1977), the size of the globin 'precursor' most easily identified for  $\beta$  mRNA is 15S, just the size expected if the insert is still present flanked by 3'- and 5'-coding regions. However, such a correlation is at best indicative. The concept of a transcribed insert is also, however, supported by the puzzling fact that both the poly (A) sequence at the 3' terminus of the mRNA and the methylated 'cap' at the 5' end seem to be conserved from the HnRNA to the final polysomal mRNA. The explanation of this is clear if the processing occurs not from one end or the other, but out of the middle.

If the inserts are transcribed, there must be a very accurate enzymatic mechanism for cutting them out. Such excision enzymes are known (Robertson & Dickson, *Brookhaven Symp. Biol.* **26**, 240–266; 1975), but have never been demonstrated in animal cells, although ribosomal RNA processing certainly involves similar accurate cleavages. The inserts might be expected to contain extensive self-complementary double-strand regions, such as palindromes, but they do not self-reassociate (at least for rabbit  $\beta$ -globin genes), indicating that if such sequences are present, they are quite short. Also, the inserts may be repeated a few times throughout the genome (Flavell and Jeffreys feel 10–15 times is the highest reiteration frequency their data might support), but are certainly not common to many structural genes. Perhaps the excision specificity is mediated by nuclear protein which, in interacting with HnRNA, would both force certain RNA conformations and also act as additional markers for specific enzymes—or even have enzymatic activity themselves.

The second possibility is that looping out occurs at the DNA level, and the inserts are never transcribed at all. The main attraction of this idea is that, while we know little about DNA structure in active chromatin, most pos-

tulates are still possible. (It also would help to explain the difficulty in obtaining convincing and reproducible transcription from chromatin because additional factors would be required to control DNA conformation for active genes.)

Finally, it is possible that the portions of the mRNA are synthesised separately and then ligated together during processing. In this case the 'inserts' might or might not be transcribed, but the various bits of the coding sequence would not be co-transcribed in a single long piece of RNA. Interestingly, the gene for which the best evidence exists for the absence of HnRNA is precisely that reported here—McKnight and Schimke (*Proc. natn. Acad. Sci. U.S.A.* **71**, 4327–4331; 1974) demonstrated that it is very difficult to show an ovalbumin HnRNA, using techniques which seem to work for globin.

No doubt we shall soon know whether the 'insert' is transcribed, and perhaps have definitive data on its multiplicity in the genome and whether it includes short palindromic signals which might indicate looping-out sites. Such experiments will be most interesting for globin, where chromatographic techniques allow the isolation of precursor RNAs (*News and Views* **269**, 9; 1977).

It is very interesting to compare these data for globin and ovalbumin genes with that reported last month in these columns (*News and Views* **269**, 648; 1977) for mouse immunoglobulin genes. In the case of Ig, there are also inserts, in DNA from antibody-synthesising tissues and from other tissues, but the inserts appear different, and at least some somatic gene reassortment takes place. For globin and ovalbumin there is no apparent difference between tissues making the mRNA and those completely inactive for the protein in question. The inserts may allow novel somatic recombination events to occur, but do not make them obligatory. It is also unclear whether these sequences are related to the leader sequences which are transcribed from remote regions of the genome in adenovirus and SV40 (*News and Views* **268**, 101; 1977).

Let us briefly consider some of the wilder possible implications of this finding. If transcripts are ligated together during processing, there is no need that they be arranged in the 'correct' order—from 5' to 3'—in the genome. In fact, genes could exist with a single 5' end and several 3' ends, which are used interchangeably or in sequence during development. Maybe the  $\beta$ - and  $\delta$ -globin genes or the two  $\alpha$ -globin genes share some parts in common, only the 'different' bits being ligated in the right proportions. If transcribed, the inserts must be (how

easily we fall into such formulations, in spite of these findings) nicked out intact; the more reason to think they could have other regulatory functions. However, if not transcribed, surely as indicated above, the inserts are now the best candidates for marker sites for binding gene-specific non-histone proteins, and thus determining chromatin conformation during the control of transcription.

Those of us who are interested in safety with recombinant DNA sequences are left with the following thought. Until now, it has been assumed that cDNA derived from an mRNA is less likely to be expressed

(and therefore, in some contexts, might be regarded as 'safer') than a total gene sequence, including the flanking regions. Now with the discovery of gene inserts it is quite likely that the controls involved in transcribing and/or processing several different bits of DNA into highly complex precursors of RNA, followed by excision and ligation steps, will be beyond the capabilities of the bacterial hosts used for recombinant DNA vectors. Hence the genomic DNA recombinants may prove to be just as safe as cDNA recombinants unless much work goes into inserting processing systems as well. □

which is much the strongest emission line in the solar spectrum. The coincidence between the Lyman- $\alpha$  frequency and that of the nearby line in the  $H_2$  spectrum is not exact but the Lyman- $\alpha$  line is so broad that there is overlap.

It is natural to ask whether there are other molecular fluorescence spectra waiting to be found in astrophysics. A general argument suggests the chance is high—molecular energies and transitions are numerous because of the many rotational and vibrational states, so that the chance of a coincidence with a transition of an atom or another molecule is much higher than for atomic spectra. It is, for example, not out of the question that a specific fluorescence process might be responsible for inverting populations of levels in the ground state of a molecule from which microwave stimulated emission occurs (Cook *Nature* **210**, 611; 1966); indeed the process suggested by Litvak (*Astrophys. J.* **156**, 471; 1969) for infrared pumping of the hydroxyl maser is of this type, although it relies on the hydroxyl itself to filter continuous radiation and produce a distribution of intensity that gives rise to selective fluorescence. Furthermore, as Jordan and others themselves mention the selective absorption of Lyman- $\alpha$  by interstellar molecules may be important in the formation of interstellar spectra of molecules (Osterbrock *Astrophys. J.* **136**, 359; 1962; Black & Delgarno, *Bull. Am. Astron. Soc.* **6**, 444; 1974).

The other question which is raised by the analysis of Jordan and others is the part played by molecules in stellar atmospheres. If molecules are at all abundant they will affect the absorption of radiation in an atmosphere in two ways. In the first place, there will be continuous absorption leading to dissociation and the frequencies for dissociation are in general much less than those for ionisation of atoms or molecules. Second, molecular lines often lie so close together because of the many rotational and vibrational states that exist, that in some parts of the spectra absorption in discrete lines will come close to continuous absorption. Molecules will of course be dissociated if the temperature of the atmosphere is high but many molecules can exist at temperatures up to 3,000 K. It has indeed been suggested that hydroxyl may contribute to the opacity of the solar atmosphere, and it is almost certain that  $H_2$  is present in cool stars where molecules such as  $C_2$  and CN are already observed.

The study of Jordan and others and the ideas which stem from it call attention to the importance of molecular spectra in the neighbourhood of Lyman- $\alpha$ . Because the energies lie above the dissociation energy of most

## Molecular hydrogen in the Sun

from A. H. Cook

A RELATIVELY large proportion of matter in galaxies lies in the space between stars and until fairly recently appeared to be in the form of free atoms and solid grains. Atoms were detected in two ways—by the microwave radiation from the hyperfine transition in the ground state of hydrogen at 1,421 MHz and by absorption of starlight by atoms showing up the spectra of the stars in the visible region. Solid particles scatter, polarise and absorb visible light from stars. There was also evidence for the existence of a few molecules, CH and CN in particular, absorption lines of which lay in the visible. It was also well known that some molecules, such as  $C_2$ , TiO, and CN occurred in cool stars. By and large however, limitations on the sensitivity of radio measurements and the restriction of optical spectroscopy to the visible meant that direct evidence of the existence of molecules could not be obtained. At the same time, dynamical considerations indicated that there was more mass in the Galaxy than could be accounted for by the observed hydrogen and other atoms.

So far as interstellar material goes, there are now extensive observations of molecules. Radio observations show absorption or emission by almost 50 molecules, a few of which radiate by maser action. Ultraviolet spectra of stars especially those obtained by the Copernicus satellite (Morton *Phil. Trans. R. Soc.* **A279**, 299; 1975) show

absorption by the  $H_2$  molecule. The abundance of interstellar  $H_2$  molecules can also be estimated from the radio observations of carbon monoxide. It is now plain that molecules are important in two ways. Many different molecules are observed in the clouds of gas that seem to be condensing into stars and the total mass of hydrogen as molecules and atoms is much greater than that as atoms alone.

Are molecules as important in stars? Clearly they are significant in the outer layers of cool stars. Now, in this issue of *Nature* (page 326) Jordan *et al.* describe their identification of  $H_2$  in the ultraviolet spectra of sunspots. The lines are in emission between 120 and 160 nm, and only a few of the possible lines of the  $H_2$  spectrum in that range are observed. Jordan and others show that the observed lines are just those to be expected if a particular level is preferentially populated by the absorption of the Lyman- $\alpha$  radiation of atomic hydrogen, which is of course very intense in the solar atmosphere. Selective fluorescence, as this process is, is of course familiar in laboratory studies. It is also known in astrophysics.

The spectra of molecules in comets are fluorescent spectra excited by sunlight, but again, not all possible lines occur. As was shown by Swings, the reason is that some energy levels are not excited because the frequencies of the transitions by which they would be excited from the ground state coincide with strong Fraunhofer lines in the solar spectrum. That is the reverse of the present case, where the upper level in the  $H_2$  spectrum is populated by absorption of a single line, Lyman- $\alpha$ ,

A. H. Cook is Jacksonian Professor of Natural Philosophy in the University of Cambridge.

molecules, predissociation phenomena may be observed in the spectra. The advent of synchrotron sources for ultraviolet spectroscopy makes it easier to investigate molecular spectra in the far ultraviolet, and prompted by the increasing astrophysical interest in molecules, it may be that there is an

area of physics here ripe for development. Thus the study of Jordan and others calls attention to these aspects of molecular astrophysics—the role of molecules in stellar atmospheres, the formation of molecular lines in interstellar formation and the expanding interest in laboratory investigations. □

## How should earthquakes be quantified?

*from a Correspondent*

At the meeting of the International Association of Seismology and Physics of the Earth's Interior (IASPEI) held in Durham on 9-19 August, 1977, a special workshop on the subject of Quantification of Earthquakes was organised by Professor K. Aki (Massachusetts Institute of Technology).

MUCH of the discussion in this workshop was concentrated on the concept of seismological magnitude, the oldest and most widely used measure of the size of earthquakes. Although magnitude has been an extremely useful phenomenological tool, recent advances in seismic source theory have convinced many seismologists that it is, if not obsolete, at least in need of revision and redefinition. There seems to be no agreement about how magnitude can be related to the physics of earthquakes or even about what it is that magnitude is intended to measure.

Also at Durham, the Subcommittee on Magnitude of the Commission on Practice met and wrestled with the problem of organising and simplifying the profusion of differing magnitude scales in current use. This task is almost impossibly difficult, due to variations in instrument design, wave types used, seismogram-reading practices, frequency and distance correction methods, and nomenclature. The situation has become so complex that even to catalogue current practices has required a major effort and has resulted in a document of impressive size. If the Subcommittee succeeds even partially in reducing the confusion and in standardising practices, it will have performed a valuable service.

Seismological magnitude was originally developed by Gutenberg and Richter in the 1930s as a heuristic tool for studying Southern California earthquakes. Before then, statistical studies of earthquake occurrence had made no distinction between large and small events, and often produced very misleading results. Magnitude was defined as proportional to the logarithm of the maximum excursion produced on a Wood-Anderson torsion seismograph

situated 100 kilometres from the epicentre, with magnitude 0 set at a level near the smallest detectable earthquakes. (Magnitudes down to about -3 are nowadays reported in micro-earthquake studies.) In this definition, Gutenberg and Richter were influenced considerably by the stellar magnitude scale in astronomy, from which seismological magnitude differs in two respects. First, and most trivially, the scales run in opposite directions: bright stars have small magnitude numbers, but great earthquakes have large ones. More importantly, seismological magnitude is intended to measure only the size of earthquakes, while astronomical magnitudes are of two varieties: absolute, which measures the total radiation from stars, and visual, which measures their brightness as seen (usually) from the Earth. The closest thing seismology has to visual magnitude is intensity, which is a measure of the strength of ground shaking in the epicentral region. Seismological intensity, however, is not based on any kind of measurement, but rather on human judgement applied to the social and engineering effects produced. It does not lend itself to quantitative interpretation, and in fact is usually expressed in Roman numerals to discourage any such attempt. As strong-motion seismographs become more widely distributed, it will become possible to place intensity on a more objective foundation. A first step in this direction might be to establish an instrumental scale for intensities below the threshold of perceptibility, where seismographic data are plentiful.

Gutenberg and Richter themselves seem to have been surprised at the great success of the magnitude concept, much of which no doubt stems from the fact that the range of magnitudes is enormous, so that even an imprecise scale is still quite useful. Detectable earthquakes range over more than 11 orders of magnitude, while even a gross blunder such as doubling the observed signal amplitude adds only 0.3 to the magnitude. By now however, our understanding of earthquake mechanisms has advanced to the point where

several physical attributes can be determined, at least approximately, from the radiated waves (such as source dimensions, displacement dislocation and stress drop). The relation between any of these quantities and magnitude is purely statistical, and subject to a great deal of scatter. (There is a case in California of a magnitude 3 earthquake with a fault length usually typical of magnitude 6 events.) It has become clear that several numbers are needed to describe an earthquake's size, and that magnitude is not one of them.

One of the most serious deficiencies of magnitude as it is now defined is the phenomenon of saturation. To determine the size of an earthquake, it is necessary to use waves longer than the spatial dimensions of the source. Otherwise, one measures only the radiation from a small part of the total source region at each instant. As a result the magnitude measured in any given instrumental pass-band has a practical upper limit. For 'short-period' (~1 s) waves this limit is around magnitude 7, while at 20 s it is about 8.5. If magnitude is based on the longest observable waves, then values range at least as high as 10 (for the 1960 Chilean earthquake). One solution to the saturation problem is to use waves longer than the source dimensions (how long this may be will vary from event to event). The quantity so measured is referred to as 'seismic moment', and its use has spread rapidly since its introduction some 10 years ago. It has the additional advantage of being subject to a simple physical interpretation: for a shear fault, for example, it is the product of the rigidity modulus, the fault area, and the mean dislocation across the fault. Seismic moment suffers, however, from being based only on low-frequency motions. In many contexts, such as that of hazard evaluation, high-frequency motions are more important.

Another related limitation of magnitude is the fact that it is based on instantaneous measurements. Signals of the same amplitude, whether they last for 1 cycle or 100, always lead to equal magnitudes, though they certainly do not correspond to similar source processes or hazards. Recently, local earthquake magnitude scales based on signal duration, or 'coda length', have been developed and are used widely in California, but they have not yet been given a sound theoretical foundation; the coda length observed is primarily a wave-propagation (scattering), rather than a source effect and may be subject to large variations with seismic region and focal depth. Coda-length magnitude has so far been used more to avoid problems of instrument saturation than to study the actual duration of earthquakes.

Considerable attention in the workshop was given to a generalisation of seismic moment, the 'seismic moment tensor.' This representation of seismic sources, which was suggested by Gilbert in 1970 (*Geophys. J. R. astr. Soc.* **22**, 223) and has recently been justified rigorously by Backus and Mulcahy (*Geophys. J. R. astr. Soc.* **46**, 341; and **47**, 301), promises to narrow the gap between observational seismology and the theory of earthquakes. The problem of understanding the earthquake process is one of the most difficult in mathematical physics, involving the elastic and anelastic behaviour, chemistry, and thermodynamics of rocks, and their interaction with the dynamic stress field. Seismologists are still far from solving this problem, and are likely to remain so for some time. When earthquakes are better understood, it may be possible to 'invert' seismic observations to derive event parameters, but meanwhile phenomenological descriptions will be needed, if only to catalogue observations we do not yet understand. This need explains much of the success of the magnitude concept, as well as the promise of the moment-tensor formulation. Backus and Mulcahy have shown that a unique reconstruction of the elastodynamic source process cannot, even in theory, be made from the information carried by the radiated waves; different physical sources can excite identical waves. What can be determined is the moment-tensor density, as a function of position and time, and any indigenous source can be described this way. To go further, unjustifiable assumptions must be made about the failure mechanism. The use of the moment-tensor representation, in fact, greatly simplifies the determination of source parameters, because the wave field depends linearly on the moment-tensor components, so the methods of linear inverse theory can be used. As a practical matter, this transformation of a non-linear inverse problem into a linear one enormously simplifies computations. The moment-tensor representation thus has the three advantages of being completely general, of being the most detailed source description which does not depend on a detailed model of the failure process, and of being computationally convenient.

It seems certain that moment tensors will prove to be powerful tools for advancing our understanding of the earthquake process. Agencies producing routine earthquake catalogues, such as the US Geological Survey and the International Seismological Centre, will probably soon begin to report moment tensors for large earthquakes, and these may someday replace magnitudes as the standard measure of earthquake size. In any event, though, seismo-

logical magnitude will be with us for some time, and its ultimate replacement or modification will occur because of scientific advances, not the reports and resolutions of official committees. □

## New earthquake magnitude scale

from Peter J. Smith

ALTHOUGH more than a million earthquakes occur each year, most of the energy released comes from the very few very large ones. There is some point, therefore, in being able to determine the seismic energy from very large earthquakes with reasonable accuracy. Unfortunately, there are difficulties in doing so. It is usual to estimate seismic wave energy ( $E$ ) from an earthquake's surface wave magnitude ( $M_s$ ) using the Gutenberg-Richter equation  $\log E = 1.5 M_s + 11.8$  or very similar empirical relationships derived by others (most notably Båth). The problem is, however, that for a great earthquake, which in this context means one with a rupture length of more than 100 km, the measured  $M_s$  is suspect.

The reason is that  $M_s$  is conventionally determined using surface waves with a period of about 20 s or by empirical conversion from a body wave magnitude derived from waves with even shorter periods. But when the rupture length of an earthquake exceeds the wavelength of the seismic waves used in the magnitude determination, the measured magnitude no longer reflects the entire rupture process; and there is then little correlation between  $M_s$  and rupture length. So the  $M_s$  scale is subject to 'saturation' at its upper end, the result of which is that for great earthquakes the measured magnitude and the energy estimated from it may be inaccurate.

In an attempt to circumvent this difficulty, which has been known for some time, Kanamori (*J. geophys. Res.* **82**, 2981; 1977) has now adopted a different approach to the calculation of the energy released by a great earthquake, an approach which leads incidentally to a more appropriate magnitude scale for such events. He thus begins not with magnitude but with seismic moment, a static source parameter defined as the product of the rigidity of the rock in the fault zone, the average slip over the fault surface and the area of the fault slip.

Peter J. Smith is a Reader in the Department of Earth Sciences at the Open University.

Seismic moment ( $M_0$ ) is essentially a measure of the overall deformation at the earthquake source, but it can also be related to the elastic strain energy ( $W$ ) released by the earthquake. It turns out that if all the built-up stress is removed by an earthquake,  $W = W_0 \sim M_0/2 \times 10^4$ . If the stress drop is not complete the expression for  $W$  becomes more complicated and the calculated  $W_0$  gives only the minimum strain energy release. However, the situation is simplified if it be assumed, with Orowan (*Geol. Soc. Amer. Mem.* **79**, 323; 1960), that the stress remaining after the earthquake is equal to the frictional stress during faulting. In this case  $W_0$  is not only the minimum estimate of  $W$  but is also equal to the seismic wave energy ( $E$ ).

It is not clear whether or not the stress drop during an earthquake is complete; there is evidence to support either view. But there is also evidence from several earthquake studies to support the validity of Orowan's condition, which, if accepted, allows  $E$  to be determined from  $W_0$  and hence from  $M_0$ , irrespective of whether  $W_0$  is the actual or the minimum strain energy release. As for  $M_0$  itself, this quantity has been determined directly for many of the great earthquakes that have occurred since 1904, for others it may be estimated from the area of the fault plane or by other means, and for a few it may no longer be estimated at all. But whether  $M_0$  is known, by whatever means, Kanamori has determined  $W_0$  and hence  $E$ . By putting these  $E$  values into the Gutenberg-Richter equation he has then calculated magnitudes, denoted generally by  $M_w$ . In other words,  $M_w$  represents a new magnitude scale for great earthquakes, determined not directly from wave amplitude but indirectly from seismic moment.

The result is interesting. For the period 1904-76 the event with the highest  $M_w$  (9.5) turns out to have been the Chilean earthquake of 1960 ( $M_s = 8.3$ ). This was followed by the Alaskan earthquake of 1964 ( $M_w = 9.2$ ,  $M_s = 8.4$ ), the Aleutian earthquake of 1957 ( $M_w = 9.1$ ,  $M_s = 8.3$ ) and the Kamchatka earthquake of 1952 ( $M_w = 9.0$ ,  $M_s = 8.3$ ). But  $M_w$  is not always greater than  $M_s$ . For the 1920 Kansu (China) shock, for example, an  $M_s$  of 8.5 becomes an  $M_w$  of 7.8. Moreover, for many earthquakes with a rupture length of about 100 km,  $M_s$  and  $M_w$  are in fairly good agreement, suggesting that for these and smaller events the  $M_s$  scale is entirely appropriate. This also means that the  $M_w$  scale connects smoothly to the  $M_s$  scale to which it becomes a natural continuation.

The  $M_w$  scale seems to be better for earthquakes because it removes the saturation inherent in the  $M_s$  scale.

But it also draws attention to some possibly significant relationships which either were not previously apparent or are different from those implied by the use of the  $M_s$  scale. For example, when  $W_0$  is plotted against time for the period 1920–76 (for which the data are almost complete) it becomes clear that the annual average for the period 1920–65 (within which  $W_0$  peaks) is more than an order of magnitude higher than that for the periods 1920–50 and 1965–76. This picture is quite different from that based on  $E$  calculated from  $M_s$ , which shows a steady decrease since the mid-1940s. The significance of this difference becomes clear with the discovery that the  $E$ -from- $M_s$  curve is very similar in shape to the corresponding time curve of the number ( $N$ ) of earthquakes with  $M_s \geq 7.0$ . Since the  $N$  curve is heavily biased in favour of moderate-to-large earthquakes, the proportion of events

with  $M_s > 8.0$  being small (3.3%), the implication is that the  $E$ -from- $M_s$  curve is also biased in favour of moderate-to-large earthquakes, indicating that for great earthquakes the seismic wave energy calculated from  $M_s$  is indeed underestimated.

This being the case, it becomes clear from a comparison of the  $W_0$  and  $E$ -from- $M_s$  curves that the number of, and the wave energy radiated by, moderate-to-large earthquakes decreased sharply just when the energy from great earthquakes increased sharply. Was this just a coincidence or was there a causal link there somewhere? The evidence suggests the latter. As Kanamori demonstrates, there is a remarkable correlation between the  $W_0$  curve and the curve of Chandler Wobble amplitude, with  $W_0$  moving in the same way as, but slightly behind, the amplitude.

One possible explanation for this correlation is that an increase in Chandler Wobble amplitude, brought about by external (for example, atmospheric) forces, triggers worldwide seismic activity and accelerates plate motions, eventually leading to great plate-decoupling earthquakes which so decrease intraplate and interplate stresses that moderate-to-large earthquake activity declines. On the other hand, the activity of great earthquakes could produce the Chandler Wobble, although this seems to be less likely. Then a third possibility is that the Chandler Wobble and great earthquakes have a common cause such as perturbations in the Earth's rotation. Whatever the explanation may be, the ancient controversy over the precise connection, if any, between earthquakes and Chandler Wobble has evidently been revived. □

## New look for Loess Commission

from I. J. Smalley

Commission 4 of the International Union of Quaternary Research (INQUA) met at Birmingham University on 16 and 23 August, 1977. The scope of the Loess Commission is to be expanded, and practical aspects of loess investigation will be emphasised.

LOESS is essentially a silty soil, widely believed to have been deposited by the wind and is of particular interest as the soil on which some of the earliest agriculture flourished. The aims of the Loess Commission have been to produce a map showing the distribution of loess in Europe and to untangle some of the stratigraphic problems presented by the thick loess sequences of central Europe. It was formed as a subcommission at the 1961 INQUA meeting in Warsaw and upgraded to full commission status at the 1969 Paris meeting. Julius Fink (Austria) was its first president and he has steered the commission to the virtual completion of its initial tasks (see *Eiszeit. u. Gegenwart* **27**, 220; 1976). At Birmingham, progress on the loess map was reported by G. Haase (DDR); the western sheet is virtually complete and proof prints should be available by the end of 1977. The eastern sheet has been delayed by the lack of a suitable topographic base but with the help of I. P. Gerasimov (USSR) this difficulty has now been overcome. Details of the map scales and the data presented are given in a paper by Haase, Ruske (DDR) and Fink which will appear soon in *Petermanns Geog. Mitt.*

Fink reported on field trips since the last congress (Christchurch 1973); visits have been made to Germany (BRD, 1974), France (1975) and the Soviet Union (Ukraine and Moldavia, 1976). Now that the European problems have been tackled the commission is looking east to the Asian loesses and the 1976 trip to Soviet territory represents the first tentative

move in that direction. The commission will also turn to the study of more practical aspects of loess and give some emphasis to irrigation problems and engineering and economic topics. New INQUA bye-laws require sweeping changes in the commission membership and advantage will be taken of this to reflect new interests (both topical and regional). The new president is Marton Pecs (Hungary), Director of the Geographical Institute of the Academy of Sciences in Budapest; vice-president, B. Frenzel (BRD); secretary, O. Fränze (BRD); and a group representing Europe: J-P. Lautridou (France), J. Fink (Austria), J. Macoun (Czechoslovakia), A. E. Dodonov (USSR) and I. J. Smalley (UK). R. V. Ruhe (USA) will co-ordinate activities in North America and J. M. Bowler (Australia) will do the same for the Australasian and Pacific regions; there are eighteen corresponding members.

J. M. Bowler reported on the contacts between Australia and China. A group from the Australian National University has visited the classic loess

regions of north China and returned with samples and Chinese loess literature. Important papers will be translated and published in English. In particular the major works by Liu Tung-sheng and his collaborators will be made available. Chinese investigators have visited Australia to look at aeolian sediments in the central regions. There is no loess as such in Australia but the aeolian sediments have enough features in common to make comparative studies worthwhile. The contact at present is established at governmental level but the commission hopes to participate in studies of one of the world's most fascinating and still problematical (see *News and Views* **267**, 484; 1977) loess deposits.

Pecs rounded the meeting off with a personal view of new aims for the commission. He stressed the need for research into practical problems connected with loess and proposed that in the next phase of the commission's activities there should be some emphasis on foundation problems and related engineering topics, on problems of landscape deterioration in loess areas, and on problems of forecasting and planning for land use. Traditional activities should not be neglected however and it might be possible to investigate certain loess stratotypes very thoroughly—perhaps on an international basis. He proposed that the section at Paks in Hungary might receive the same intense study as that organised by Fink at Krems in Austria.

The next loess discussion will probably be in Jerusalem at the Sedimentological Congress in July 1978. D. H. Yaalon (Israel) will prove to doubters that desert loess exists. □

I. J. Smalley is a Lecturer in the Department of Civil Engineering at the University of Leeds.

## Evolution of ageing

T. B. L. Kirkwood\*

*An evolutionary view of ageing suggests that mortality may be due to an energy-saving strategy of reduced error regulation in somatic cells. This supports Orgel's 'error catastrophe' hypothesis and offers a new basis for the study of normal and abnormal ageing syndromes and of apparently immortal transformed cell lines.*

THE question of why we and most other higher animals age is not trivial since many organisms, notably higher plants, live and propagate indefinitely. Perhaps because we are so familiar with ageing it is dangerously easy to fall into circular argument such as that ageing is a mechanism for ridding a population of old and worn-out individuals who would otherwise compete for resources with younger and fitter ones<sup>1</sup>. This makes sense if, for example, we assume individuals to have a defined reproductive lifespan, but is circular since the cessation of reproduction is itself a phenomenon of ageing. In this paper I show that by adopting an evolutionary point of view it is possible to relate Orgel's theory<sup>2</sup> that ageing is the result of a progressive breakdown in accuracy in protein synthesis to recent theoretical and experimental work on the senescence of diploid human fibroblasts, and I suggest a new reason why we may expect the error theory of ageing to be correct.

In discussing the evolution of error regulatory mechanisms it is appropriate to begin with brief consideration of the emergence of the earliest life-forms. The fate of the first replicating organic molecule would have depended on the speed and accuracy with which it generated 'daughters'. Subject to a continual risk of disruption by chemical and physical agents in the environment the lifetime of any relatively complex molecule must have been strictly limited. In addition primitive replication was probably highly inaccurate so only a relatively small proportion of copies would have been viable. To avoid extinction a replicator needed to produce at least one viable copy before being disrupted and even so there remained a definite chance of extinction which decreased inversely with the expected number of descendants per generation. It is, therefore, highly unlikely that life began all at once in a particular place at a particular time. Much more plausibly large numbers of colonies of different replicators were appearing and disappearing over the same period of time. Gradually, and inevitably, the colonies became larger as the faster and more accurate replicators outlasted the others. The mean levels of accuracy and speed of replication continued to rise while the freely available raw material for biosynthesis was depleted, leading to intensive interspecies competition and strong selection for catalytic activity and hence, for example, to the evolution of organised cells capable of binary fission.

### Coping with errors

At a fundamental level evolutionary survival is the preservation of a dynamic balance between information, or

order, and entropy, or disorder. Indeed, given the capacity for replication, neo-Darwinist natural selection may be seen as the direct result of interaction between the information stored in living organisms and the entropy of their environment. The diversity of present-day species testifies to the wide range of evolutionary strategies that are effective for survival, and it is my intent in this paper to demonstrate why ageing should be one of these.

A vital manifestation of entropy is the error inherent in all processes of macromolecular information transfer within living cells. To sustain the prospect of further evolutionary change and so improve its chance of ultimate survival an organism must make occasional copying errors. Too many mistakes would be a serious handicap so what is needed is a compromise, a tolerable level of error sufficient to allow necessary change. Given enough time natural selection ensures that organisms with optimal error levels will dominate. The presence of any error at all, however, poses interesting problems for our understanding of molecular biology.

Orgel<sup>2</sup> pointed out that cellular proteins could be divided roughly into two sets, those involved in the transfer of information from DNA, in replication and in protein synthesis, and those involved in other cell functions. The presence of a low level of error in the synthesis of the second set of proteins would have relatively little effect on cell viability. But erroneous synthesis of some of the first set might have serious consequences since abnormal proteins that retained activity but had reduced specificity could produce further defective proteins and so generate a positive feedback of errors leading to a progressive decline in the accuracy of the protein-synthesising machinery and ultimately to a lethal 'error catastrophe'. Orgel subsequently revised<sup>3</sup> his original suggestion that the error frequency must increase exponentially and showed that depending on the amount of error feedback allowed, stability of translation may be achieved despite the presence of error. In some circumstances, however, error catastrophe would still occur. Hoffman<sup>4</sup> has proposed a more detailed model of the feedback of errors in the protein-synthesising machinery and concluded that translation is too stable to allow 'error catastrophe' to play any real part in present-day organisms. He supposes the translation apparatus to comprise a set of polypeptide 'adaptors' responsible for inserting amino-acids into a peptide chain according to the sequence specified by the DNA. The average accuracy of the  $i$ th generation of adaptors (assuming these to be in some sense discrete generations)—that is the probability that an adaptor of the  $i$ th generation inserts the correct amino-acid—is denoted by  $q_i$ . Then what matters is the form of the functional relationship between  $q_i$  and  $q_{i-1}$ . If  $q_i > q_{i-1}$  the error level

\*National Institute for Biological Standards and Control, Holly Hill, London NW3 6RB.

## Complete accuracy

Fig. 1 A simplified model<sup>4,5</sup> of the feedback of errors in the translation apparatus assumes a set of polypeptide "adaptors" to be responsible for inserting the specified amino acids into peptide chains. The curves illustrate the form of relationship between the average accuracy,  $q_i$ , of the generation  $i$  adaptors and the average accuracy,  $q_{i-1}$ , of the immediately preceding generation. The arrow indicates the direction of displacement of the curve as the average proportion ( $R$ ) of activity retained by erroneous adaptors decreases.

decreases while if  $q_i < q_{i-1}$  it increases. According to Hoffman the dependence of  $q_i$  on  $q_{i-1}$  is S-shaped with a region where  $q_i > q_{i-1}$  for any plausible present-day apparatus. The presence of this stable region forms the basis of Hoffman's conclusion that 'error catastrophe' is not relevant to present-day organisms. Kirkwood and Holliday<sup>6</sup> point out, however, that Hoffman's model requires that the activity of an erroneous adaptor be reduced to a level so low that feedback of errors is virtually prohibited and argue that a considerable body of biological evidence does not support this assumption. They define a parameter  $R$  that represents the proportion of activity retained by erroneous adaptors and show that the value of  $R$  determines whether or not stability is attained (see Fig. 1), low values of  $R$  resulting in stability (Hoffman's model is equivalent to the case where  $R$  is fixed and very small). The introduction of this parameter into the model is of great importance since it allows a degree of freedom on which evolution may work. For example, the development of a 'scavenging' system that would degrade erroneous protein would reduce the value of  $R$ .

It should immediately be recognised that this model is a great oversimplification and cannot be viewed as anything more than a broadly descriptive account of the possibilities of error catastrophe or stability. It does, nevertheless, serve to illuminate the general qualitative features that can be expected of the feedback of errors in the protein-synthesising machinery and it forms a useful basis for discussing their relevance to the evolution of present-day organisms.

As primitive cells evolved, each containing its own translation apparatus, some stability of error must have been achieved. Error catastrophes may, of course, have been initiated in some daughter cells but the expected number of 'catastrophe-free' offspring per generation must have been greater than one. Selection would have favoured those cells with the highest proportion of 'catastrophe-free' offspring and so increased the level of stability.

This can be understood quite easily in terms of the Kirkwood/Holliday model. As  $R$  (the proportion of activity retained by erroneous adaptors) decreases the S-shaped

curve relating to  $q_i$  to  $q_{i-1}$  moves steadily upwards and to the left. Thus an  $R$ -value can be chosen such that the curve just touches the line  $q_i = q_{i-1}$  giving a point of precarious balance. A slight further decrease in  $R$  produces a small stable region ( $q_i > q_{i-1}$ ). Random fluctuation in  $q$ , however, may allow a jump across the stable region into incipient error catastrophe. Decreasing  $R$  decreases the chance of such a jump. Thus we can see that selective pressure continues to reduce  $R$  until the chance of jumping across the stable region becomes very small. This would have been particularly true for organisms exposed to environments where the risk of externally introduced errors was high.

On this basis we can expect to find that in present-day organisms the stability of translation will be very high. At this point, however, it is important to draw a distinction between unicellular and multicellular organisms. In discussing ageing our attention is confined to the latter in which the cells may be grouped as somatic cells which do not contribute information to succeeding generations and germ line cells which do. We shall see that there are good reasons why an organism should have evolved a different approach to error regulation in these two categories of cells and that these are sufficient to explain why we age.

### The phenomenon of ageing

Since Hayflick and Moorhead<sup>6</sup> gave the first clear demonstration that human fibroblast cells have a finite lifespan *in vitro* these cells have been studied as a possible model for ageing *in vivo*. Fibroblast lifespan has been shown to be determined largely by cell generations and not by chronological time<sup>7</sup>, and Martin *et al.*<sup>8</sup> have proved that the finite division potential is related to ageing *in vivo* by demonstrating that culture lifespan declines with donor age. A similar conclusion was indicated by the finding that cells from patients with diseases of premature ageing showed reduced division potential.

Senescent fibroblasts are visibly sick and cannot compete with young cells. It is therefore surprising that cellular selection does not act against the senescent cells leaving the culture permanently viable. The most satisfactory explanation is that cells become 'committed' to senescence while still outwardly healthy and that a number of cell generations then elapse before the death of the resultant clone. A model on these lines has been shown to explain the finite lifespan of human fibroblasts in culture<sup>9</sup>. This model is very simple in structure. It is assumed that any cell not yet committed to senescence gives rise to committed daughter cells with some probability  $P$  for each daughter and that an incubation period of  $M$  cell generations is required before death. If  $P \geq 0.5$  the expected number of uncommitted daughters per uncommitted cell is  $\leq 1$ , so mortality is inevitable. If  $P < 0.5$  the uncommitted cells can in principle increase in number. In practice, however, the culture size is strictly limited and surplus cells are discarded with the result that the uncommitted cells are lost 'by dilution' unless the culture size is very large (routine cultures contain  $10^6$ – $10^7$  cells). Experimental results<sup>10</sup> strongly support this model and suggest that  $P \approx 0.275$  and  $M \approx 55$ – $60$ .

The conclusion we might be tempted to draw from the observed mortality of cell cultures, namely that ageing *in vivo* is the result of the body's cells simply running out of division potential, is denied by the data of Martin *et al.*<sup>8</sup> which show that mean culture lifespan (population doublings)  $\approx 42 - 0.2 \times$  donor age so that cells from even 90–100-yr-old individuals are capable on average of 20–25 population doublings. A specific feature of the commitment model is that it predicts a sharp fall in the cell population growth rate as the first committed cells reach the end of their incubation period and die (see Fig. 2) since these constitute approximately a quarter of the population. For normal cell cultures the change of growth rate may be

expected 20–25 population doublings before the end of the culture lifespan. Tissue in old people may therefore be experiencing this fall in growth rate. This conclusion is supported by the estimated value of 55–60 cell generations for the incubation period which allows  $\approx 10^{17}$  cells to be produced from a single cell before the change in growth rate would occur, a number reasonably close to the total number of cells likely to be required in a normal human lifetime. Ageing is a complicated process and it may be a mistake to seek too simple an explanation. It is, however, possible that the relatively sudden loss of a substantial proportion of cell replicative potential may account for the physical emaciation and loss of homeostasis associated with senile decay.

### Why grow old?

The commitment model closely resembles the model for the feedback of error in the protein synthesising machinery if we equate  $P$  with chance of jumping from a stable to an unstable state and  $M$  with the metabolic period required for an error catastrophe to result. Fifty-five to sixty cell generations may seem surprisingly long in this context, but  $q_i$  initially changes slowly and it can be shown that many generations of adaptors may have to elapse before  $q_i$  falls very far.

Experiments show that increasing the error frequency reduces the lifespan of human fibroblasts<sup>11</sup> and that old cells contain higher levels of erroneous functional and translational enzymes than young cells<sup>11,12</sup>. A general error catastrophe thus offers a plausible explanation for the ageing of human fibroblasts. That it offers a likely explanation may be seen from the following argument.

As Hamilton and others have recently emphasised (see ref. 13) natural selection must operate at the level of the replicating unit, the gene. To maximise their chance of survival genes must always replicate between succeeding generations as rapidly and accurately as allowed by their environment. Accuracy can only be achieved through the

expenditure of energy, either by direct proof-reading, kinetic proof-reading as proposed by Hopfield<sup>14</sup>, or by destroying erroneous products. The latter may occur either at a molecular level by scavenging for erroneous protein or at a cellular level by means of a 'suicide' protein that kills the cell when the error level begins to rise<sup>2,15</sup>. Accuracy in the germ line is vital for gene survival but a high level of accuracy in somatic cells may be a luxury our genes do better to forego. Ageing may, therefore, be the result of an energy-saving switching off of the mechanisms responsible for high accuracy in the translation apparatus at or around the time of differentiation of somatic cells from the germ line. This may leave the somatic cells in a relatively unstable state where a small random increase in errors commits them to an eventual error catastrophe.

This strategy is evolutionarily stable in the sense defined by Maynard Smith and Price<sup>16</sup> provided that the risk to the individual of accidental death is not too low since the alternative of maintaining the high accuracy in all cells which might allow immortality would carry the penalty of an increased energy requirement. This penalty would mean that, other things being equal, an individual would grow and reproduce more slowly or would be subject to a greater risk of starvation or accidental death while seeking food.

### Conclusions and implications

There are three requirements for a satisfactory theory of ageing. It must be theoretically plausible, it must be supported by experimental evidence, and it must make evolutionary sense. The general error theory satisfies all these requirements. The main rival theory suggests that ageing is genetically programmed in much the same way as morphogenesis. Although this is theoretically plausible no specific model has been proposed that is amenable to experimental test and no convincing argument has been put forward to favour the evolution of such a programme. A further theory<sup>17</sup> suggests that ageing is the result of natural selection delaying the time of onset of deleterious genes, so that senescence and death result from the accumulation of late-acting harmful genes. This well-argued theory is, however, either circular or incomplete as it presupposes ageing in a general sense since the time of action of a gene during adulthood is determined not by chronological time but by its biochemical environment. If the time-keeping process is a genetic 'clock' the theory is identical with the programme theory. If it is an increase of errors it may be incorporated as a part of the general error theory. A third possibility, that the genes are triggered by the accumulation (or depletion) of some otherwise innocuous substance, would need to be specifically defined and tested before it could be seriously entertained.

If the argument presented here is correct, we may hope to understand some of the many aspects of ageing by detailed study of the processes of error regulation. We may examine how different species have adapted these processes to meet their individual needs and, in particular, we may hope to gain insight into the abnormalities represented by diseases of premature ageing and by the apparently immortal transformed cells of malignant tumours. It may, for example, be possible that oncogenic viruses interfere with these processes to enhance the accuracy of their own replication in a way that restores some error-committed cells to stability. Such a return to a quasi-germ-line state might explain the reappearance of foetal proteins in malignant tissue. We should remember too that our ageing processes evolved at a time when our average lifespan was considerably shorter, just long enough in fact for us to fulfil our basic evolutionary role of bearing children and nurturing them to reproductive age. In modern technological societies the majority of us reach old age and mortality need not necessarily be evolutionarily stable.

I am very grateful to Dr R. Holliday for continued help

**Fig. 2** Predicted fall in cell population growth rate according to a model of the commitment to senescence of diploid human fibroblasts<sup>9</sup>. Cells not yet committed are assumed to give rise to committed daughter cells with probability  $P$  ( $\approx 0.275$ ) for each daughter.  $M$  ( $\approx 55$ –60) cell generations after commitment the resultant clone is assumed to die. An initially uncommitted population doubles with each cell generation until, after  $M$  generations, the first deaths occur and the population growth rate falls. During routine cell culture, when the population size is strictly limited, uncommitted cells are lost "by dilution" and the population dies out (solid curve). Very large cultures may, however, continue indefinitely at the reduced growth rate (broken line).

# Drift of the major continental blocks since the Devonian

E. Irving

Centre Géologique et Géophysique, Université des Sciences et Techniques du Languedoc, 34060 Montpellier, France, & Earth Physics Branch, Department of Energy, Mines and Resources, Ottawa, Canada

*Palaeomagnetic evidence indicates that the continents have been in a more-or-less continuous relative motion. At the end of the Palaeozoic there was a redistribution of the major continental blocks that occurred without the formation of new ocean between them. Wegener's Pangaea seems only to have lasted a few tens of millions of years.*

MAPS summarising the drift of the major continental blocks since the middle Devonian (–375 Myr ago) are presented here. They are based mainly on a global synthesis of the palaeomagnetic data<sup>1</sup>, including the most recent results from the USSR<sup>2</sup>. Reasonably reliable apparent polar wandering (APW) paths for the major continental blocks can now be drawn for the Middle Carboniferous (325 Myr ago) onwards, and are given in Figs 1 to 3. They have been obtained by first referring all the palaeomagnetic poles to a scale of Myr<sup>3</sup>. The oldest poles from each continental block were then grouped into an interval of 40 Myr duration, and an average calculated to obtain the oldest point. The limits of the interval were then moved forward by 10 Myr and a second average taken, and so on. Only every fourth value is independent. It would be desirable to use averages over a shorter interval, but as yet the data are neither numerous enough, nor sufficiently well spread in time. Calculations using 30 and 40 Myr intervals yielded almost identical mean values, but at 20 Myr more scatter was evident. The mean 95% errors are 6° (North America), 7° (Eurasia) and 7° (Gondwana).

The calculations were made assuming that the geomagnetic field averaged to an axial geocentric dipole (AGD). There is evidence that even when averaged over millions of years, the field may have had long-term non-dipole components<sup>4</sup> sufficient to cause polar errors of about 5°, and there are physical reasons why this might be so<sup>5</sup>. Analysis<sup>6</sup> of the geomagnetic field over the past 25 Myr yields no evidence for departures greater than about 5°. Indeed, it has recently been shown that during the Phanerozoic there is no significant departure of the field from that of an AGD within the errors in the palaeomagnetic determinations<sup>7</sup>. There is good agreement between the palaeomagnetically determined latitude and the palaeoclimatic evidence, and this supports the AGD assumption in a general

way<sup>8</sup>; for example, glaciations occur in Australia from the Middle-Carboniferous to the end of the Permian<sup>9</sup>, and their disappearance coincides with the motion of the pole away from Australia (Fig. 3). Finally, there is excellent internal agreement among Gondwana poles from localities spaced over 9,000 km, among poles from localities spread over 5,000 km in North America, and among poles spread over 6,000 km from Eurasia; note, for example, the high precision ( $k = 103$  to 406) of Gondwana poles in the interval 270 to 290 Myr ago from Argentina, Morocco, Madagascar, Tanzania and Australia (Table 1). It is unlikely that such internal agreement would have been observed within blocks that at the time were adjacent to one another, if the field really had had very large non-dipole components. Therefore there are grounds for supposing that the poles of Table 1 provide estimates of the geographical pole with an average accuracy of 6° or 7° ( $P = 0.05$ ).

Since the advent of plate tectonics, maps showing displacements of the continents have been made using evidence mainly from the oceans, information that extends back only to the early Jurassic. Such maps indicate that at about 200 Myr ago the continental crust was grouped into a single supercontinent<sup>10</sup>, referred to here as Pangaea A. Pangaea A is essentially Wegener's reconstruction<sup>11</sup>. But for how long, before 200 Myr ago, did Pangaea A exist? This may be studied by comparing the latitudes for reference localities that were once adjacent but are now far apart using the paths of Figs 1 to 3. If Pangaea A existed the latitudes should be the same. For the comparison between North America and Africa (Fig. 4) the reference locality used is midway between Cape Blanc (locality L 21°N, 19°W in the African frame) and Cape Hatteras (locality M 37°N, 74°W in the North American frame) using the most recent reconstruction<sup>12</sup> of Pangaea A;  $\Delta\lambda = \lambda_L - \lambda_M$ , and  $\lambda$  has been calculated from Table 1 using equation (9.1) of ref. 8. For the Lower Jurassic (190–160 Myr)  $\Delta\lambda$  is effectively zero, so that the palaeomagnetically determined latitudes agree with Pangaea A. Before that  $\Delta\lambda$  is positive and significant, suggesting that during the Permian and much of the Triassic, Africa had a more northerly position relative to North America than that indicated by Pangaea A. This result is independent of the choice of reference localities, and is essentially the same for other reconstructions<sup>13,14</sup>. This discrepancy, although not previously so well documented, has been known for many years, and

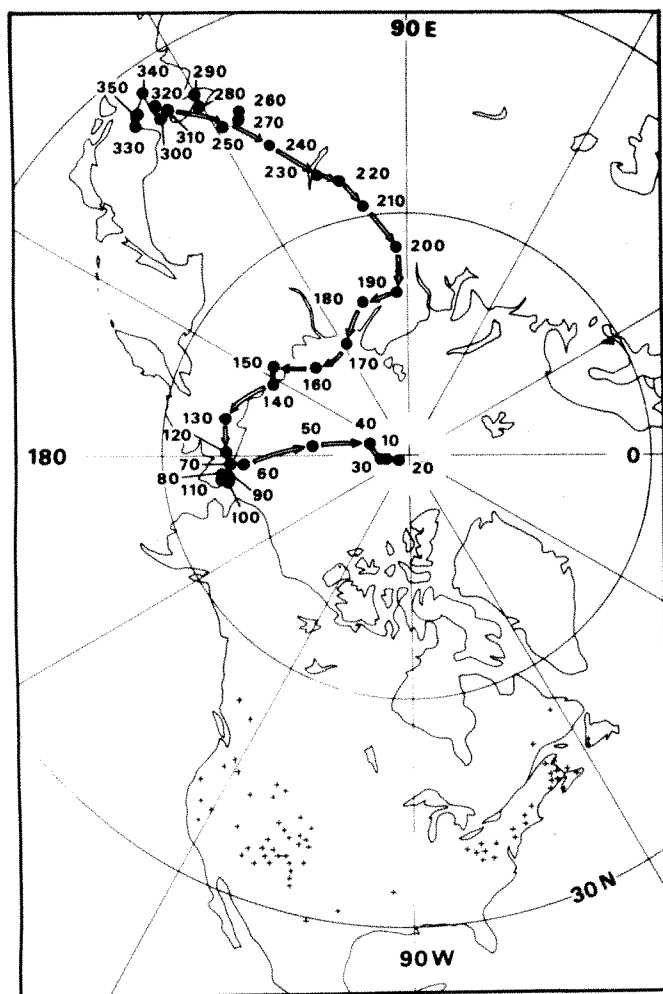

Fig. 1 Apparent polar wander (APW) relative to North America since the Devonian. Sampling localities are marked by crosses. Errors listed in Table 1.

several workers<sup>15-18</sup> have proposed that there was a large post-Triassic shear along Tethys (the Tethys twist<sup>17</sup>), that was supposed to account for the Alpine deformation<sup>16,17</sup>. This idea is no longer acceptable because the early Jurassic palaeomagnetic results are now known to be in excellent agreement with Pangaea A (Fig. 4); the motions needed to account for the discrepancy must have occurred before the Alpine Orogeny, and before the creation of the western part of Tethys in the late Triassic. For the comparison between North America and Europe the corresponding  $\Delta\lambda$  values using Orphan Knoll as the reference locality ( $P$  50°N, 47°W in the North American frame, and  $Q$  50°N, 17°W in the European frame  $\Delta\lambda = \lambda_P - \lambda_Q$ ) do not differ from zero in the Permian and lower Jurassic, but there is a significant departure of about 10° in the Triassic (Fig. 4). It has been proposed<sup>19</sup> that this is best explained by assuming that Eurasia moved southward with respect to North America during the lower and middle Triassic. Although this is probably the correct interpretation of the discrepancy itself, it alone does not explain the remarkable fact that later, in the lower Jurassic, the results are again in excellent agreement with Pangaea A (Fig. 4). Tectonic explanations for the discrepancies of Fig. 4 that are globally compatible with all the available palaeomagnetic data are now presented.

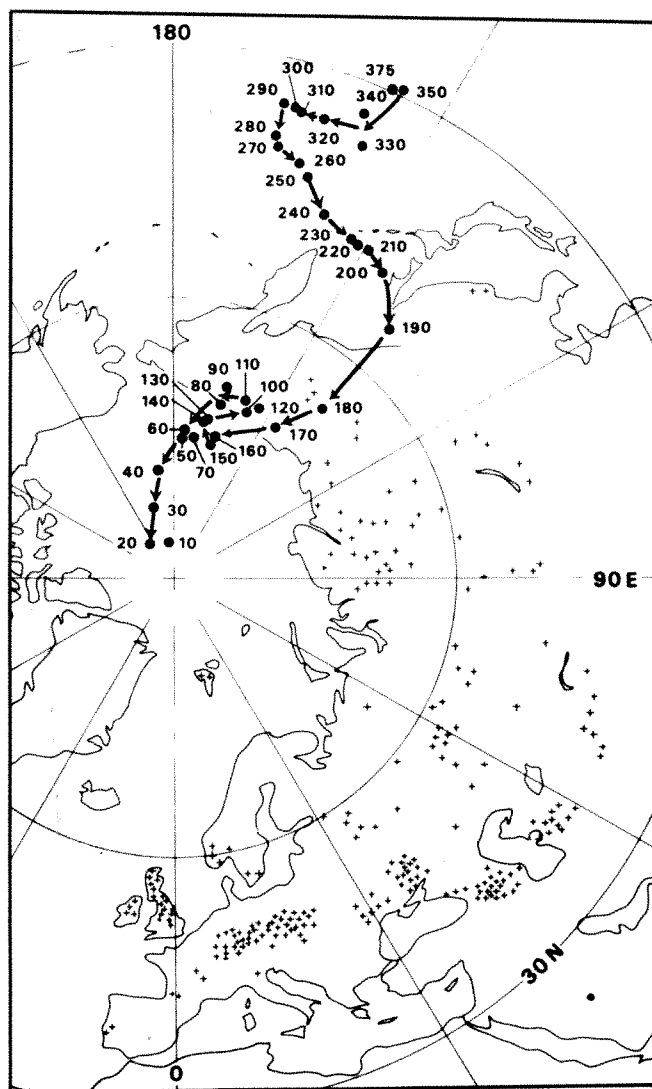

APW paths define the latitudes and azimuths but not the longitudes of continents. In order to obtain maps for post-Pangaea A time (200 Myr ago) the latitudes of the continents have been fixed palaeomagnetically, and their relative longitudes have, for the most part, been taken from plate tectonic reconstructions<sup>10,20-22</sup>. Maps for times before 200 Myr ago have

been made by working backwards, interval by interval, from Pangaea A, maintaining consistency with the palaeomagnetically determined latitudes and azimuths, but restricting relative motions to a minimum and disallowing major overlap between continents.

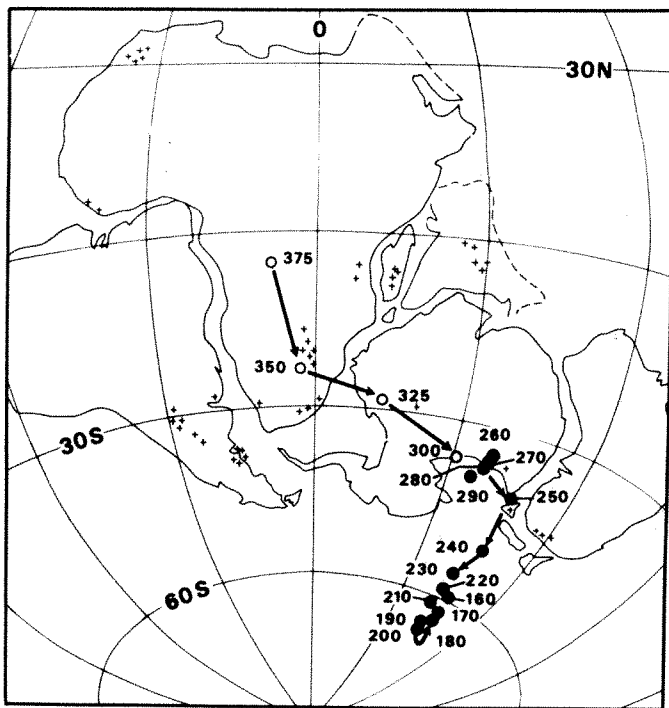

### Description at maps

The suggested reassembly for the mid-late Devonian (375 Myr ago) is shown in Fig. 5a. In the north there is a more-or-less coherent supercontinent, Laurasia, consisting of the Laurentia, Baltic-Russian and Siberian cratons and their bordering Early Palaeozoic foldbelts. Several authors<sup>27,28</sup> have argued that in the Devonian there was a wide ocean on the site of the Ural foldbelt. But, the palaeomagnetic poles from the Devonian of the Russian and Siberian platforms, are in reasonable agreement, and therefore it is assumed that there was no more than a narrow trough between them. The mean Devonian pole for the Russian platform is 32°N, 161°E,  $\alpha_{95} = 5^\circ$  (5.120), for the Dneister region it is 39°N, 161°E,  $\alpha_{95} = 7^\circ$  (5.130), for the Ural region it is 38°N, 165°E,  $\alpha_{95} = 9^\circ$  (5.177) and for the Siberian platform 24°N, 149°E,  $\alpha_{95} = 8^\circ$  (5.178). (The numbers in brackets refer to entries in ref. 1 where the bibliography and analytical details may be found.) Because of the longitude indeterminacy this solution is not a rigorous one, but only the simplest, which devolves from the constraint of minimum

Fig. 2 APW relative to northern Eurasia since the Devonian. See legend Fig. 1.

**Fig. 3** APW relative to Gondwana for the Late Palaeozoic and Early Mesozoic. ●, Are the poles of Table 1 and have been obtained by statistical analysis; ○, for the interval 375 to 325 Myr ago, are approximate poles, obtained by visual inspection of sparse data from Australia and South America only. This interpretation follows that given in refs 43, 45 and 46, and is speculative. Gondwana began to split in the Jurassic, and an average path cannot be obtained for later times. See legend Fig. 1.

motion. If the Urals are the site of a collision between the two platforms it seems more likely that the major movement occurred in the early rather than the late Palaeozoic. This problem is not of direct interest in the present context and will be considered again later (Morel and Irving, in preparation). In the late Devonian assembly of Fig. 5a Spitzbergen adjoins Ellesmere Island and Greenland<sup>23</sup>, and northern Alaska is rotated with respect to North America<sup>24,25</sup>. There is at present no palaeomagnetic information from the northern two-thirds of Alaska that would shed light on this speculation, but there is indirect evidence. In the Mid-Cretaceous (100 Myr ago) the pole positions relative to Eurasia and North America make it impossible to place them together without substantial overlap of their continental shelves (Figs 1 and 2). Alaska, or NE Siberia, or both have moved. Chukotsk<sup>26</sup>, with or without the Kolyma block (Irving and Geuer, in preparation), may have been continuous with northern Alaska. It is possible that all three elements (northern Alaska, Chukotsk and Kolyma) moved together, their tectonic juncture with Asia being the huge fault systems of the Khrebet Cherskogo. Alternatively, Kolyma may have been welded on to Asia separately<sup>34</sup>, and this is accepted here. The possible position of NE Siberia relative to northern Alaska is indicated by *H*? in Fig. 5. A further feature of Fig. 5a to *i* is an indentation in the northern border of Laurasia. This is the Sinus Borealis, or proto-Arctic, which closed in the early Cretaceous (see below). To the south of Laurasia there may have been an ocean about 2,000–3,000 km wide (see legend to Fig. 5). The southern continents are assembled into a supercontinent, Gondwana<sup>29</sup>.

In the zone of interaction between Laurasia and Gondwana, the positions of many crustal elements are uncertain. For example, Spain and central Europe may have been situated in position *B* or *C* (see ref. 30) of Fig. 5, and the USA south and east of the Appalachians could have occupied either positions

*A* or *B*. The best recent data<sup>31</sup> favour position *B* for southern France. The data from Spain are indecisive. Nor is very much known about the positions of Iran, China<sup>32</sup> and southern Indo-China. This paper is concerned with the major continental blocks and no detailed consideration of these questions is given.

At the Devonian–Carboniferous boundary, Laurasia and Gondwana are converging and they meet in the Mid-Carboniferous. The relative longitudes of Fig. 5c were chosen so as to minimise their subsequent relative motion. Africa is opposite

**Fig. 4** Latitude differences ( $\Delta\lambda$ ) for reference localities from North America and Gondwana (above), and North America and Europe (below), for the later Palaeozoic and Early Mesozoic using the reconstruction of Pangaea B<sup>12</sup>. See text for method of calculation. The errors at ( $P = 0.05$ ) are given. The approximate durations of Pangaea A and B are marked. *T* is the suggested time of opening of the western Tethys.

Europe, and South America opposite North America. This is referred to as Pangaea *B*. A similar reconstruction for the Permian has recently been given independently by Westphal<sup>34</sup>, and the earliest record of it is in ref. 9 (Fig. 10, 17). There are, however, no palaeomagnetic constraints on longitude, so Gondwana could have been further east, or it could have been situated west of North America. These optional configurations<sup>17,18</sup> are considered less likely because the subsequent motions needed to achieve the known late Jurassic configuration (Fig. 5i) would have been greater—a factor of two greater in the latter instance. In Gondwana the Samfrau<sup>29</sup> super-foldbelt develops. It extends for 6,000 km from the Tasman foldbelt, through the Ellsworth and Cape foldbelts to the central Andes. By the end of the Carboniferous the fit between Laurasia and Gondwana tightens, and apparently remains unchanged in the early Permian, although small adjustments, undetectable palaeomagnetically, could be occurring (Fig. 5d to *f*).

At the Permian-Triassic boundary the palaeomagnetically determined latitudes now allow Gondwana to rotate anticlockwise, and the transformation from Pangaea *B* to *A* to begin. This is made possible by a northward movement of North America<sup>19</sup> along a zone (*XM*), located, it is suggested, between Ireland and Newfoundland, and passing north to the Sinus Borealis. By the late Triassic the rotation of Gondwana

*T* is geological time in Myr. *W* is the width of the averaging interval in Myr. *N* is the number of values used, *R* the resultant and *k* the precision<sup>48</sup>.  $\lambda, \phi$  are the latitude and longitude of the mean pole.  $\alpha_{95}$  is the 95% error. The data used are the starred entries in the Ottawa catalogues, and omitting results from deformed beds in foldbelts; for example, the selection for North America is essentially the same as that of ref. 50. Results from Speckled Sandstone of India<sup>51</sup> are also omitted. A list of the data used may be obtained from the author. The values for Gondwana have been rotated relative to Africa using the reconstruction of ref. 52.

relative to Laurasia stops, and the motion along *XM* reverses (Fig. 5*h*). North America is now locked to Gondwana, and both rotated anticlockwise relative to Europe, opening the western Tethys and forming Pangaea *A*. Mexico is assumed to move NW relative to North America<sup>33</sup>. During the transformation from Pangaea *B* to *A* it is as if Gondwana forces North America northwards out of its path, and then, carrying North America along with it, opens Tethys. The total relative motion along the Hercynian super-foldbelt is about 3,500 km. Movement is completed by the late Triassic, but its start is poorly determined. Some shear may have begun in the early Permian, and the time required may have been as long as 75 Myr (average relative velocity 5 cm yr<sup>-1</sup>). The northward movement of North America relative to Europe is at least 1,000 km, although the errors are such that the movement may be as much as 2,000 km (ref. 19). The succeeding southward movement of North America relative to Europe is of the same magnitude. The motion along *XM* is unlikely to be pure shear but also partly extensional, and one of the consequences might be the development of grabens, which, in the North Sea, contain oil. The formation of the early Triassic Siberian Traps, the dextral rotation of Novaya Zemlya, and the opening of the Kara Sea<sup>25</sup>, may also be caused by it. During the late Triassic, the Cordilleran super-foldbelt apparently develops as a continent-ocean interaction, and extends over 10,000 km from New Zealand to Alaska.

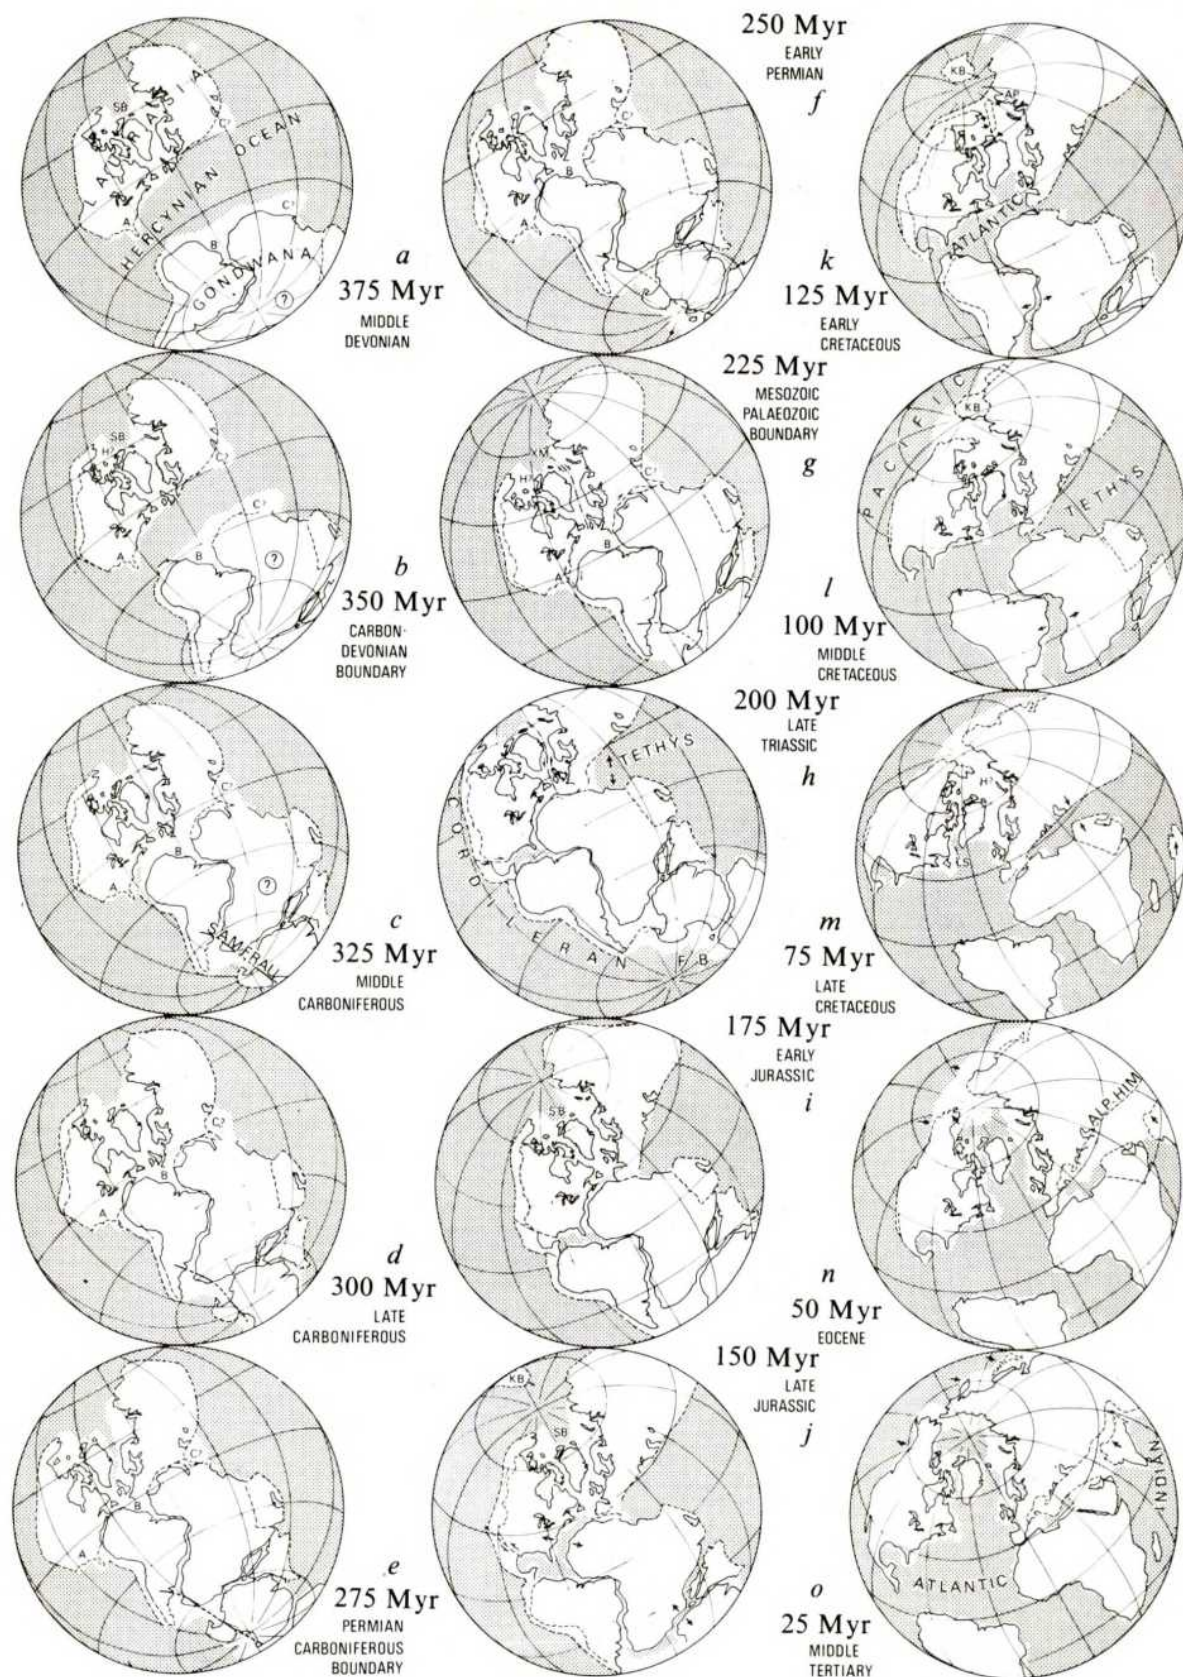

By the late Triassic or early Jurassic Wegener's Pangaea (Pangaea *A*) is achieved (Fig. 5*i*). By the mid-late Jurassic the North Atlantic begins to open, Mexico is able to achieve its present position, and a rift appears between eastern and western Gondwana. In the early Cretaceous, Sinus Borealis closes (Fig. 5*k*), and Spain begins to rotate anticlockwise. Rifting is initiated in the South Atlantic. In the Middle Cretaceous, Tethys is open to the Atlantic (Fig. 5*l*). The Kolyma Block, and surrounding Mesozoic foldbelts, could have been welded onto Eurasia<sup>27,34</sup> at this time. The region around the north pole is entirely covered with continental crust. During the late Cretaceous the Labrador Sea (*LS*) opens (Fig. 5*m*), Africa moves eastward relative to Europe, and Tethys closes to the west.

At the beginning of the Tertiary, NE Eurasia moves away from North America, allowing northern Alaska and parts of NE Siberia to rotate anticlockwise and open the Canada Basin (Fig. 5*n*); the Canada Basin could therefore be a back-arc basin formed by the migration of a thin sliver of continental crust over the NW Pacific subduction zone. India moves northward, and the Alpine-Himalayan super-foldbelt forms. By the mid-Tertiary, Alaska completes its rotation (Fig. 5*o*), the Atlantic rift system is fully developed, and the Alpine-Himalayan super-foldbelt is established in its present form.

## Discussion

The maps are presented as an explanation of the palaeomagnetic record. They have been constructed by adhering to the AGD assumption, within the statistical errors, that are within the limits for non-dipolar fields as they are presently known<sup>6</sup>. The maps indicate that Wegener's Pangaea lasted only a few tens of Myr, and that in the Permian and Mesozoic major continental blocks of North America, Eurasia and Gondwana were in more-or-less continuous motion relative to one another. Other workers, however, have taken a less mobilistic view, and their maps differ in two important respects. Firstly their maps<sup>49</sup> show the Arctic to be a static region throughout the Mesozoic, the bordering continents of North America and Eurasia being fixed relative to one another. But geologically the Arctic is far from static. There are foldbelts, rifts, subsiding basins and thick igneous sequences, that in other contexts would be taken as evidence of plate motions. Secondly, in most contemporary maps Wegener's Pangaea is regarded as inviolate in the Permian and Triassic, and the palaeomagnetic discrepancies of Fig. 4 are attributed to the presence of large non-dipole components in the geomagnetic field<sup>28,35,36</sup>, so that the palaeomagnetic pole

**Fig. 5** Continental drift since the Devonian. The latitudes of the major continents have been fixed by placing the palaeomagnetic poles (within their 95% error circles) at the poles of the projection using Geuer's Terrascope<sup>17</sup>. This rule is relaxed for *g* and *h* because it is not yet possible to provide satisfactory maps for the *B* to *A* transformation; the necessary details are unlikely to be revealed until a shorter averaging interval can be used, perhaps 20 Myr. *A*, *B* and *C* signify possible positions for micro-continents between Laurasia and Gondwana (see text); *AP* possible zone of subduction during closure of Sinus Borealis *SB*; *H*? possible position of the Chukotsk peninsula relative to Alaska; *KB* Kolyma Block; *LS* Labrador Sea; *XM* suggested location of Triassic shear zone between Europe and North America. The question-marks in Africa in *a*, *b* and *c* draw attention to the possible error in latitude determinations for Gondwana for the Devonian and Early Carboniferous, that arises from the uncertainty in the Devonian and Early Carboniferous pole path for Gondwana (Fig. 3). The width, indeed the existence of the 'Hercynian Ocean', is uncertain. This figure is an attempt to map the movements of the major continent blocks relative to one another and to the pole. No attempt is made to map the positions of minor blocks, and the boundaries of some of the major blocks (for example, North-East Gondwana, and South-East Asia) are highly speculative.

determinations, even when derived by averaging results from many rock units distributed over a large continental block, would be in error by as much as 20°. There is, however, excellent agreement between the palaeomagnetically determined latitudes and plate tectonic reconstructions for the Lower Jurassic onwards (Fig. 5*i* to *o*), so that if such large non-dipole components were present, they seem to have disappeared at the beginning of the Jurassic. There is no other evidence for such a change. Although the hypotheses of an inviolate Pangaea and large non-dipole fields in the late Palaeozoic and Mesozoic are still tenable, it is argued here that the alternative tectonic explanations of Fig. 5 are more reasonable; it would be a coincidence if the non-dipole fields were of exactly the form to produce the apparent latitude differences between North America and Eurasia at just the right time to allow the transformation from Pangaea *B* to *A* to occur, followed by the creation of Tethys when required by the geological evidence.

The concept of a mobile Pangaea provides a framework within which to discuss geological events. The Hercynian–Appalachian super-foldbelt could have developed as a result of the collision of Laurasia and Gondwana<sup>30</sup>. It is cut by large right-lateral wrench faults<sup>37,38</sup> and it has been suggested<sup>37</sup> that they were caused by the relative right-lateral displacement of Laurasia with respect to Gondwana; the displacement is estimated to be 600–1,000 km, and to have occurred between 290 and 250 Myr ago. It post-dates the main Hercynian Orogeny. The sense of displacement is the same, but it is three times less, and apparently began about 40 Myr earlier, than that of Fig. 5. Therefore there could be two diastrophic phases, the smaller earlier displacement of ref. 37 being followed by the larger displacement described here. The two phases could have overlapped in time. The earlier displacements at first met much resistance, and hence were slow and small, and were responsible for most of the observable geological strains. Once a zone of weakness was established, rapid displacements occurred, accompanied by less stress, and fewer observable geological effects. The location of the zone of weakness is not known, but it may have been between Spain and Morocco, and the Brevard Zone of the southern Appalachians is also a possible site. Alternatively, the dating of either the palaeomagnetic results, or the movements along the wrench faults, may be in error. Such large systematic errors are possible, but unlikely. Although the maps of Fig. 5 provide the framework for the discussion of the western part of the Hercynian super-foldbelt between Laurasia and Gondwana, they do not do so for the eastern part situated in central and eastern Asia. It is perhaps worthy of note that palaeomagnetic results from Malaya<sup>32</sup> and China<sup>1</sup> indicate that these blocks were in latitudes of 10 to 20°N during the Permian, and therefore they could have been situated in the eastern embayment between Africa and Asia (Fig. 5*e*). They could have formed part of one or more blocks that interacted with the southern edge of the Siberian craton to form the eastern part of the Hercynian super-foldbelt.

Pangaea *B* existed from the middle of the Carboniferous to the end of the Palaeozoic, about 80 or 90 Myr. It presumably indicates a special type of mantle convection at that time. It corresponds in time to the late Palaeozoic reversed interval (the Kiaman of ref. 39) when changes in the polarity of the geomagnetic field were very infrequent. The significance of this correlation can only be guessed. The onset of the *B* to *A* transformation coincides, within the accuracy of the age estimates, with the onset of frequent reversals at the end of the Permian. This first-order change in the geomagnetic field was probably a response to topographic or temperature changes at the core–mantle interface, and hence to changes in the lower mantle<sup>40,53</sup>. The *B* to *A* transformation differs from other known Phanerozoic drift episodes in that it does not seem to involve the creation of spreading ridges and new oceans between the major continental blocks. The absence of known spreading ridges is a possible cause of the worldwide regression at the end of the Permian. Exposure of the continental shelves, which house a high proportion of biological activity, could have

been the major environmental change responsible for the widespread extinctions at the end of the Palaeozoic<sup>41</sup>. The changes that occurred in mantle convection at the end of the Palaeozoic could have been responsible for both the sudden increase in reversal frequency, and the *B* to *A* transformation, and the latter, in its turn, caused the late Permian extinctions. The identification, made here, of a first-order episode of continental drift, that commenced at the very end of the Palaeozoic or earliest Triassic, may therefore be the major cause of the geological break between the Palaeozoic and Mesozoic. This drift episode, whose main feature was a dextral shear between the northern and southern continents about the palaeoequator, may also reflect a major change in mantle convection which produced what is perhaps the most important change in the geomagnetic field yet recorded.

Finally, the geological evidence indicates that during the late Palaeozoic there was apparently no ocean between Europe and Gondwana<sup>42</sup>, and Tethys did not open until the early Mesozoic (Fig. 5 *g* and *h* agree well with this evidence).

I thank F. Arthaud, R. Black, F. Brun, J. Geuer, J. Hastie, P. Louis, M. Mattauer, P. Matte, D. F. Strong, J. Sweeney, P. Tapponier and K. Whitham, for their help.

*Note added in proof:* Recent palaeomagnetic studies in the Brooks Range have shown the anticlockwise rotation of northern Alaska<sup>55</sup>, thus confirming the indirect arguments given above.

# X-ray bursts and neutron-star thermonuclear flashes

P. C. Joss

Department of Physics and Center for Space Research, Massachusetts Institute of Technology, Cambridge, Massachusetts 02139

*Some of the properties of thermonuclear flashes that should occur in the surface layers of accreting neutron stars are investigated. Such flashes may account for many of the observed properties of X-ray burst sources. Helium seems to be the most promising type of nuclear fuel for producing flashes that result in X-ray bursts.*

THE history of the discovery of X-ray burst sources has been described by Grindlay<sup>1</sup>, and their observed properties have been reviewed by Lewin<sup>2</sup> and Lewin and Joss<sup>3</sup>. These sources emit bursts of X-rays with risetimes of  $\lesssim 1$  s and decay time scales of  $\sim 3$ –100 s. If they are at a mean distance of  $\sim 10$  kpc, as suggested by their apparent concentration towards the direction of the galactic centre, then the X-ray energy emitted in each burst is typically  $\sim 10^{38}$ – $10^{40}$  erg. The maximum luminosity during the course of a burst is roughly equal to the Eddington limit for a  $1 M_{\odot}$  object ( $\sim 10^{38}$  erg s<sup>-1</sup>). The recurrence intervals between bursts are generally in the range  $\sim 10^4$ – $10^5$  s, except for the 'rapid burster' MXB1730–335 (ref. 4) which has recurrence intervals of  $\sim 10$ –100 s. Many, if not all, burst sources undergo extended inactive states lasting for weeks or longer, during which no bursts are seen. At least eight burst sources also seem to be associated with relatively steady X-ray sources, to within positional accuracies of  $\sim 0.1^{\circ}$ . The ratio,  $\alpha$ , of 'steady' X-ray luminosity to time-averaged burst luminosity is as large as  $\sim 250$  for the associated sources, but an upper limit as small as  $\alpha \lesssim 2$  has been placed on one burst source (MXB1730–335) with no identified steady counterpart.

A theoretical model of X-ray burst sources must account for these observations. Some models that have been suggested invoke mechanisms involving massive black holes<sup>5,6</sup> or instabilities in the accretion on to a compact object of roughly solar mass<sup>7–12</sup>. Here we discuss another type of model: the production of X-ray bursts by thermonuclear flashes in the freshly accreted matter near the surface of an accreting neutron star.

This model was first proposed by Maraschi and Cavaliere<sup>13</sup> and Woosley and Taam<sup>14</sup>. Even before the discovery of X-ray burst sources, the possibility of thermonuclear flashes on accreting neutron stars was considered by Hansen and Van Horn<sup>15</sup>. The present paper investigates further some of the physical processes relevant to such flashes in the context of the rapidly growing volume of observational information. This discussion is still highly preliminary, as realistic numerical calculations of such flashes have not yet been carried out; in particular, the characteristic timescale between flashes is unknown. We conclude that thermonuclear flashes may account for some, but not all, of the observed X-ray burst sources. Our discussion also considers why observational evidence has not yet been obtained for thermonuclear flashes in X-ray pulsars, which are also very likely to be accreting neutron stars. A discussion of some of the same points, including the physics of nuclear fusion processes in accreting neutron stars and the energetics of thermonuclear flashes, has been presented independently by Lamb and Lamb<sup>16</sup>.

## The physical picture

We consider a neutron star undergoing accretion of mass from a binary stellar companion. The infalling matter will be rich in hydrogen and/or helium. But, in the interior of the neutron star (density  $\rho \gtrsim 10^7$  g cm<sup>-3</sup> or depth  $h = R - r \gtrsim 10^2$  cm (see ref. 15),

where  $r$  is the distance from the centre of the neutron star and  $R$  is the neutron-star radius), nuclear reactions will proceed rapidly even at zero temperature and the nuclei will tend towards a state of nuclear statistical equilibrium. As the infalling matter accumulates, a given element of mass will pass through increasing density and must release the nuclear binding energy associated with the transmutation from its initial composition to a composition of iron-peak elements. If the accreted matter is pure hydrogen, then the energy released will be  $\sim 8 \times 10^{18}$  erg g<sup>-1</sup>.

If the neutron star is cold (internal temperature  $< 10^7$  K) and if the gravitational energy released by accretion is radiated away sufficiently rapidly, then the first reaction to proceed will be either pycnonuclear fusion or electron capture by protons at  $\rho \approx 10^7$  g cm<sup>-3</sup>, ultimately producing helium<sup>17</sup>. At somewhat higher densities, fusion of helium into heavier elements will proceed. These processes may occur quasi-statically<sup>18</sup>, especially if the temperature is very low<sup>17</sup>. If, however, either the accretion rate or the internal temperature of the neutron star is sufficiently high, then the fusion will be thermally unstable and should result in a thermonuclear flash; the thermonuclear runaway time scale for such a flash is usually  $\lesssim 1$  s (ref. 15). If the energy released in a flash can be transmitted to the neutron-star surface sufficiently rapidly and then lost as electromagnetic radiation, an X-ray burst will result.

We use here the models of Hansen and Van Horn<sup>15</sup> for neutron stars that are undergoing spherically symmetric accretion and steady-state nuclear burning, to estimate the conditions in the surface layers just before a flash. The actual conditions in the surface layers will be somewhat different in the absence of steady-state burning, but more accurate estimates cannot be made until time-dependent calculations of neutron-star envelopes undergoing nuclear burning are carried out.

## Energetics

Several useful constraints on thermonuclear-flash models can be derived from simple energetic considerations.

The gravitational energy per unit mass liberated by the accreting matter is given by  $E_a = (GM/R) = \eta_a c^2$ , where  $M$  is the mass of the neutron star, and  $\eta_a \sim 0.2$  is the ratio of released gravitational energy to rest-mass energy. (The value of  $\eta_a$  may be as small as  $\sim 10^{-3}$  or as large as  $\sim 0.4$ , depending upon the mass of the neutron star and the equation of state of matter at high densities.) This energy will be radiated away from the neutron-star surface with a time-averaged luminosity

$$L_a = \dot{m} E_a \approx 2 \times 10^{37} \left( \frac{\eta_a}{0.2} \right) \left( \frac{\dot{m}}{10^{17} \text{ g s}^{-1}} \right) \text{ erg s}^{-1} \quad (1)$$

where  $\dot{m}$  is the time-averaged mass accretion rate. In the case of the neutron stars that are the X-ray emitting components of binary X-ray pulsar systems, this luminosity is evidently emitted mostly as X radiation.

Nuclear fusion will also contribute to the total luminosity of an accreting neutron star<sup>18</sup>. The energy per unit mass released by nuclear fusion can be written as  $E_n = \eta_n c^2$ , where  $\eta_n$  is the energy efficiency of the reaction;  $\eta_n \approx 7 \times 10^{-3}$  for conventional stellar fusion of pure hydrogen (PP chains or CNO cycle),  $\eta_n \approx 1 \times 10^{-3}$  for helium-burning, and  $\eta_n \lesssim 1 \times 10^{-3}$  for the burning of heavier elements. As discussed below, full hydrogen-burning will not occur in a neutron-star thermonuclear flash, and we therefore

expect that in general  $\eta_n \lesssim 1 \times 10^{-3}$ . If X-ray bursts are caused by thermonuclear flashes in the accreted matter, then the ratio of the time-averaged accretion luminosity to the time-averaged luminosity in bursts is given by

$$\alpha_{\text{flash}} \simeq 2 \times 10^2 \left( \frac{\eta_n}{0.2} \right) \left( \frac{\eta_n}{10^{-3}} \right)^{-1} f^{-1} \xi^{-1} \quad (2)$$

where  $\eta_n$  is the efficiency factor appropriate to the nuclear reactions that participate in the flash,  $f$  is the fraction of the nuclear fuel that is consumed in flashes (rather than during the interflash periods), and  $\xi$  is the fraction of the flash energy that is transmitted to the neutron-star surface (rather than lost to the interior). The values of  $f$  and  $\xi$  are unknown, but we shall make the reasonable assumption that both quantities are of order unity. Thus, if the accretion on to the neutron star is steady on a timescale of hours or longer, then we expect that the time-averaged 'steady' X-ray flux from the neutron star will exceed the time-averaged burst flux by at least a factor of  $\sim 10^2$ .

It is also necessary that the accreted mass be sufficiently large to supply the thermonuclear energy of the flash. If a steady state has been established between the accretion of nuclear fuel by the neutron star and its consumption in flashes, then this constraint can be expressed as

$$\epsilon_B \simeq 9 \times 10^{38} \left( \frac{\eta_n}{10^{-3}} \right) \left( \frac{\dot{m}}{10^{17} \text{ g s}^{-1}} \right) \left( \frac{\tau}{10^4 \text{ s}} \right) f \xi \text{ erg} \quad (3)$$

where  $\epsilon_B$  is the average total energy emitted in each burst and  $\tau$  is the average time interval between bursts. (Only a fraction of the envelope above the burning shell need be consumed in a given flash, so that the total mass  $\delta m$  of the overlying surface layers may exceed  $\dot{m}\tau$  by a substantial factor.) If  $\dot{m}\tau$  is actually much less than  $10^{21} \text{ g}$ , then the flashes will be weak and will not produce observable X-ray bursts. The nuclear energy generation rate required to supply the flash energy  $\epsilon_B/\xi$  is given by

$$q_{\text{nuc}} \gtrsim 10^{17} \left( \frac{\epsilon_B}{10^{39} \text{ erg}} \right) \left( \frac{\delta m}{10^{21} \text{ g}} \right)^{-1} \left( \frac{\tau_B}{10 \text{ s}} \right)^{-1} f^{-1} \xi^{-1} \text{ erg g}^{-1} \text{ s}^{-1} \quad (4)$$

where  $\tau_B$  is the timescale of duration of the burst emission.

The energy of the flash is thermalised as it is transmitted to the neutron-star photosphere (see below), so that the characteristic photon energy of the burst will be

$$\begin{aligned} e_\gamma &\simeq 4k(\epsilon_B/4\pi\sigma R^2\tau_B)^{1/4} \\ &\simeq 6 \left( \frac{\eta_n}{10^{-3}} \right)^{1/4} \left( \frac{\dot{m}}{10^{17} \text{ g s}^{-1}} \right)^{1/4} \left( \frac{\tau}{10^4 \text{ s}} \right)^{1/4} \left( \frac{\tau_B}{10 \text{ s}} \right)^{-1/4} \times \\ &\quad \times \left( \frac{R}{10^6 \text{ cm}} \right)^{-1/2} f^{1/4} \xi^{1/4} \text{ keV} \end{aligned} \quad (5)$$

The indicated values of  $\epsilon_B$  and  $e_\gamma$  for the chosen plausible parameter values are consistent with the observed properties of X-ray burst sources.

## Nuclear reactions

We first consider hydrogen-burning as a possible source of nuclear energy. The density at the base of a steadily burning hydrogen-rich layer will be in the range  $10^4 \lesssim \rho_b \lesssim 10^5 \text{ g cm}^{-3}$  (ref. 15). (We shall use  $\rho_b$  and  $T_b$  to denote the density and temperature at the base of a layer of any specified nuclear fuel.) It seems probable that  $\rho_b$  will not lie very far outside this range even if the burning is unsteady.

For the PP chains, the reaction rate is too slow at any temperature to release the energy in a time  $\lesssim 10 \text{ s}$ , as would be required to account for the short timescales of the observed bursts. The CNO cycle is unable to operate fully, because the  $\beta$  decays of the intermediate nuclei ( $^{13}\text{N}$ ,  $^{15}\text{O}$ , and  $^{17}\text{F}$ ) require timescales of  $\sim 10^2$ – $10^3 \text{ s}$ . There are no known  $\beta$ -unstable excited states of any of these nuclei that could be thermally populated and thereby appreciably shorten the  $\beta$ -decay timescales, nor will the timescales be effectively reduced, at the expected densities, by captures of continuum electrons. Some of the  $\beta$ -unstable nuclei will undergo

additional proton captures during the flash, provided that the temperatures attained are sufficiently high ( $\gtrsim 10^9 \text{ K}$ ). The resultant reaction chains for initial  $^{12}\text{C}$ ,  $^{14}\text{N}$ , and  $^{16}\text{O}$  nuclei are as follows:

where  $\bar{E}$  is the average energy liberated per proton capture (excluding the average neutrino loss, if any). The  $\beta$ -decay half life of  $^{18}\text{Ne}$  is 1.5 s, so that this nucleus can decay sufficiently rapidly to continue through the reaction chain on a timescale less than  $\tau_B$ . Of course,  $^{13}\text{C}$ ,  $^{15}\text{N}$  and other heavier nuclei will participate in similar reaction chains, but their initial abundances are likely to be lower than those of  $^{12}\text{C}$ ,  $^{14}\text{N}$ , and  $^{16}\text{O}$ . (The daughter nuclei of  $^{14}\text{O}$  and  $^{15}\text{O}$  may be important if the same layer of matter participates in more than one flash, but this consideration does not substantially alter the expected values of  $\eta_n$ .)

An average of  $\sim 2$  protons will be consumed for each CNO nucleus, and the amount of energy liberated per CNO nucleus will be  $\sim 8 \text{ MeV}$ . Hence, if the duration of flash-burning is no greater than the observed duration of an X-ray burst, then the energy efficiency of the protonisation of CNO nuclei will be  $\eta_n \sim 9 \times 10^{-3} N_{\text{CNO}}$ , where  $N_{\text{CNO}}$  is the fractional abundance by number of CNO nuclei in the unburned matter. (We assume that  $N_{\text{CNO}} \lesssim 0.3$ .) This value of  $\eta_n$  will be increased slightly by proton captures on to other heavy nuclei and will also be increased by  $\alpha$ -captures, which should occur at the high temperatures attained in the flash. The value of  $\eta_n$  will thus depend on the temperatures achieved during the flash, as well as on whether the same layer of accreted matter participates in more than one flash. If the CNO abundance is near the cosmic value of  $N_{\text{CNO}} \sim 10^{-3}$ , however, then the energy efficiency of a hydrogen-burning flash should generally be quite low.

If, instead, the flash is caused by the fusion of helium or heavier elements, then the reaction rates will not be retarded by the effect of weak interactions and the reactions can proceed very swiftly ( $\ll 1 \text{ s}$ ) when sufficiently high temperatures are achieved. (The relevant nuclear reaction rates are not greatly affected by relativistic effects, electron degeneracy effects, or electron screening, so that conventional reaction-rate formulae may be used.) The energy efficiency of helium-burning is no lower than that of hydrogen-burning, unless the CNO abundance in a hydrogen-burning flash is extremely high ( $N_{\text{CNO}} \gtrsim 0.1$ ).

The value of  $\eta_n$  in a flash of helium or heavier elements may be increased by convective mixture. For example, such mixing could draw hydrogen into a helium-burning shell and result in proton-captures on to the heavier nuclei that are being synthesised.

Neutrino loss rates will be highest if the flash occurs in helium. The models of ref. 15 suggest that  $\rho_b \gtrsim 10^6 \text{ g cm}^{-3}$  at the base of the helium-rich layer; the released energy would be sufficient to raise the temperature to  $T_b \sim 2 \times 10^9 \text{ K}$  for  $\rho_b \sim 10^6 \text{ g cm}^{-3}$  (where a substantial fraction of the internal energy would be taken up by blackbody radiation) and to  $T_b \sim 10^{10} \text{ K}$  for  $\rho_b > 10^7 \text{ g cm}^{-3}$  (where the radiation energy density would be negligible). The neutrino loss rates (ref. 19; ref. 20 and references therein) are as high as  $\sim 10^{18} \text{ erg g}^{-1} \text{ s}^{-1}$  at  $\rho_b \sim 10^7 \text{ g cm}^{-3}$  and  $T_b \sim 10^{10} \text{ K}$ , but decrease rapidly with decreasing temperature and also decrease with increasing density. The effective helium-burning flash energy and the value of  $T_b$  may thus be slightly reduced in a narrow range of densities near  $\rho_b = 10^7 \text{ g cm}^{-3}$ , but will be unaffected at other densities. At the higher densities anticipated for a flash of heavier elements ( $\rho_b \gtrsim 10^9 \text{ g cm}^{-3}$  and  $T_b \sim 10^{10} \text{ K}$ ; see ref. 14), the neutrino loss rates are negligible. They will also be negligible in a hydrogen-burning flash, since  $T_b$  will then be no greater than  $\sim 10^9 \text{ K}$  unless  $N_{\text{CNO}}$  is extremely large ( $\gtrsim 0.1$ ).

## Heat transport

If a thermonuclear flash is to produce an observable X-ray burst, then the surface layers of the neutron star must be sufficiently thick

to provide the nuclear energy of the burst. One must, therefore, also consider whether the timescale for transport of the energy of the flash to the neutron-star surface will be  $\lesssim 1$  s, as required to account for the observed rapid risetimes of the X-ray bursts.

Conduction of heat by electrons is probably unimportant even if the electron degeneracy of the surface layers is high before the flash, because the degeneracy will generally be lifted and the conductivity will become small in each layer of matter before most of the heating of the layer by the flash has occurred. Convection should be important in the development of the flash, and an estimate based on the mixing-length theory indicates that the timescale for the initial transport of heat through the convectively unstable region will not greatly exceed the sound travel time ( $\ll 1$  s). In many possible circumstances, however, convection will not transport the energy of the flash all the way to the neutron-star photosphere. We demonstrate the validity of this statement as follows.

Consider first a hydrogen-burning flash. If all of the energy is released rapidly (in a time  $\ll 1$  s), and the CNO abundance is enhanced (say,  $N_{\text{CNO}} \sim 2 \times 10^{-2}$ ), then  $\sim 4$  MeV is released for each proton consumed, and a maximum temperature of  $T_b \sim 10^9$  K may be achieved at the base of the burning shell. This result is self-consistent, since the proton-capture reactions will, in fact, proceed very rapidly at  $T_b \sim 10^9$  K. Some burning of helium and heavier elements should also occur, but the temperature will not be increased greatly over this value. At this temperature, electron degeneracy will be lifted and the flashed matter will behave as a mixture of a nearly ideal gas plus blackbody radiation. We distinguish between two cases. (1) If  $\rho_b > 10^4$  g cm $^{-3}$ , then the internal energy of the gas dominates that of the radiation and

$$\beta \equiv \frac{\text{gas pressure}}{\text{total pressure}} \gtrsim 0.9$$

Hence, as a convective element rises and cools nearly adiabatically, its temperature,  $T_{\text{conv}}$ , will depend on its density,  $\rho_{\text{conv}}$ , as

$$T_{\text{conv}} \propto \rho_{\text{conv}}^{2/3} \quad (7)$$

(2) If, instead,  $\rho_b < 10^3$  g cm $^{-3}$ , then the radiation energy density becomes significant, so that  $\beta \lesssim 0.3$ ,  $T_b$  is somewhat reduced, and

$$T_{\text{conv}} \propto \rho_{\text{conv}}^{1/3} \quad (8)$$

For the greater energy per unit mass that might be released in a flash of helium or heavier elements, degeneracy is again generally lifted; for  $\rho_b > 10^8$  g cm $^{-3}$ , one obtains  $\beta \gtrsim 0.9$  and  $T_b \sim 10^{10}$  K, while for  $\rho_b < 10^7$  g cm $^{-3}$ , one obtains  $\beta \lesssim 0.3$  and somewhat smaller values of  $T_b$ .

In all cases where  $\beta \gtrsim 0.9$ , relation (7) implies that the temperature of a convective element will have fallen to  $T_p \lesssim 10^6$  K due to its expansion by the time it has reached the photosphere. This may well be less than the ambient photospheric temperature  $T_e$ , in which case the buoyancy of a convective element will vanish at a deeper level of the surface layers and no convective heat flux will reach the photosphere. Even if  $T_p$  is in excess of  $T_e$ , it is smaller by a factor of  $\gtrsim 10$  than the photospheric temperature required to produce the X-radiation of a burst (see equation (5)). On the other hand, if  $\beta \lesssim 0.3$ , then relation (8) implies that  $T_p \gtrsim 10^7$  K, so that convection can transport heat to the photosphere with adequate efficiency to produce an X-ray burst. But, for a flash of elements heavier than helium,  $\beta$  should always be close to unity and convection should, therefore, never be able to transport heat all the way to the photosphere (compare ref. 14).

The remaining heat transport mechanism of significance is radiative diffusion. From the equation of radiative transfer in local thermodynamic equilibrium, we find that under the conditions of a flash the radiative luminosity,  $L_{\text{rad}}$ , exceeds the Eddington limit  $L_{\text{crit}}$ . This implies that the heat transport will be dominated by convection up to a level where the temperature gradient is sufficiently small to allow  $L_{\text{rad}} \simeq (1 - \beta)L_{\text{crit}}$  (ref. 21). If  $\beta \lesssim 0.3$  at

the burning shell and convection therefore penetrates to the photosphere, the radiative luminosity escaping from the photosphere should still be  $\sim L_{\text{crit}}$ . For the outer portion of the surface layers, we may thus take

$$L_{\text{rad}} \sim (1 - \bar{\beta})L_{\text{crit}} \\ \simeq 1 \times 10^{38} (1 - \bar{\beta}) \left( \frac{M}{M_{\odot}} \right) \left( \frac{\kappa}{0.4 \text{ cm}^2 \text{ g}^{-1}} \right)^{-1} \text{ erg s}^{-1} \quad (9)$$

where  $\bar{\beta}$  is the typical value of  $\beta$  and  $\kappa$  is the typical radiative opacity in the outer surface layers (expressed in units of the Thomson scattering opacity for pure hydrogen).

Let  $\rho_r$  be the density at the base of the radiative layer when the convective motions first penetrate to that layer. Using equation (7) and the equations of hydrostatic equilibrium and radiative transfer, and assuming that  $L_{\text{rad}}$  and  $\kappa$  vary slowly through the outer surface layers before the flash, we can estimate  $\rho_r$  for cases where  $\beta \gtrsim 0.9$  at the burning shell:

$$\rho_r \sim 1 \times 10^5 \left( \frac{\rho_b}{10^8 \text{ g cm}^{-3}} \right)^2 \left( \frac{T_b}{10^{10} \text{ K}} \right)^{-3} \left( \frac{T_o}{10^7 \text{ K}} \right)^3 \text{ g cm}^{-3} \quad (10)$$

Here,  $T_o$  is the temperature before the flash at the level where  $\rho = 10^2$  g cm $^{-3}$ . The indicated values of  $\rho_b$  and  $T_b$  are plausible for a helium-burning flash<sup>15</sup>, and we expect that  $T_o \sim 10^7$  K in a neutron star undergoing a moderate rate of accretion. Using equation (10) and the equation of hydrostatic equilibrium, we further find that the timescale for the initial diffusion of radiation from the base of the radiative layer to the photosphere is

$$\tau_r \lesssim \kappa \rho_r h_r^2 / c \\ \sim 0.1 \left( \frac{\kappa}{0.4 \text{ cm}^2 \text{ g}^{-1}} \right) \left( \frac{\rho_b}{10^8 \text{ g cm}^{-3}} \right)^{10/3} \left( \frac{T_b}{10^{10} \text{ K}} \right)^{-5} \left( \frac{T_o}{10^7 \text{ K}} \right)^7 \\ \times \left( \frac{M}{M_{\odot}} \right)^{-2} \left( \frac{R}{10^6 \text{ cm}} \right)^4 \mu_r^{-2} \text{ s} \quad (11)$$

Here  $h_r$  is the depth of the initially radiative layer and  $\mu_r$  is the typical mean molecular weight in the layer.

These estimates of  $L_{\text{rad}}$  and  $\tau_r$  are crude, but they indicate that convection and/or radiative diffusion should transport sufficient heat from a helium-burning flash to the neutron-star photosphere to produce an X-ray burst and that the initial risetime of the burst should be sufficiently short to agree with the observations. From equation (3), we also find that the indicated value of  $L_{\text{rad}}$  is just sufficient to give a timescale for burst emission of  $\tau_B \sim \epsilon_B / L_{\text{rad}} \sim 10$  s. The luminosity and diffusion timescale for a hydrogen-burning flash are also capable of accounting for the properties of an X-ray burst, but  $\epsilon_B$  and  $\tau_B$  will be too small and  $\alpha_{\text{flash}}$  will be too large unless the CNO abundance is considerably enhanced over its cosmic value. A thermonuclear flash of carbon or heavier elements at  $\rho_b \gtrsim 10^9$  g cm $^{-3}$ ,  $T_b \sim 10^{10}$  K, and depth  $h_b \sim 10^4$  cm (ref. 14) can reproduce the emitted energies of X-ray bursts, but may not be able to produce sufficiently short burst risetimes.

Convection will carry fresh fuel into the burning shell to feed the flash. The total amount of available fuel may therefore exceed the mass of the initial burning shell by a large factor. On the other hand, the burning will tend to be terminated by the expansion and cooling of the surface layers following the initial flash. In the absence of detailed numerical calculations, one cannot determine what the duration of the flash will be. It is plausible, however, that the expansion of the surface layers and subsequent termination of the flash will occur on a thermal timescale for the surface layers:

$$\tau_{\text{th}} \sim 10 \left( \frac{2 - \beta_s}{\beta_s} \right) \left( \frac{T_s}{10^{10} \text{ K}} \right) \left( \frac{\delta m}{10^{21} \text{ g}} \right) \left( \frac{L_{\text{rad}}}{10^{38} \text{ erg s}^{-1}} \right)^{-1} \mu_s^{-1} \text{ s} \quad (12)$$

where  $\beta_s$ ,  $T_s$ , and  $\mu_s$  are the typical values of  $\beta$ , temperature, and

mean molecular weight in the surface layers following the flash. (Note that  $\tau_{th}$  must be comparable to  $\tau_B$ , since the internal energy of the surface layers is dominated by the energy released in the flash.) If all of the available nuclear fuel is consumed in a time less than  $\tau_{th}$ , then the flash will instead terminate on a nuclear-exhaustion timescale:

$$\tau_{nuc} \sim 10 \left( \frac{\eta_n}{10^{-3}} \right) \left( \frac{\delta m}{10^{21} \text{ g}} \right) \left( \frac{L_{nuc}}{10^{38} \text{ erg s}^{-1}} \right)^{-1} f \text{ s} \quad (13)$$

where  $L_{nuc}$  is the integrated nuclear energy generation rate throughout the surface layers; one expects  $L_{nuc} > L_{rad}$  during the flash. Either (or both) of these timescales can be comparable to or shorter than 10 s, as desired if thermonuclear flashes are to account for the observed bursts.

The emergent radiation will be effectively thermalised. A  $\sim 10$  MeV photon produced in a  $(p, \gamma)$  reaction, for example, will be thermalised to  $\sim 10$  KeV after  $\sim 10^2$  scattering events. Hence, most photons generated at an optical depth greater than  $\sim 10$  will be thermalised by the time they reach the photosphere. The presence of convection should not inhibit the thermalisation; from the mixing-length theory, we estimate that a photon produced in the burning shell will generally undergo many scattering events before reaching the photosphere. Moreover, even if thermonuclear fusion spreads through most of the surface layers during the progress of the flash, a significant amount of fusion should not reach an optical depth as small as  $\sim 10$ . The transport of radiation through the accreting matter, however, may complicate the emergent spectrum, as seems to be the case for the binary X-ray pulsars (see ref. 22 and references therein).

## Conclusions

The surface layers of accreting neutron stars should undergo thermonuclear flashes that will produce unsteady radiation, and this radiation may have properties similar to those of the observed X-ray burst sources. Helium-burning flashes are the most promising type for producing X-ray bursts, because of the relatively high energy yield and because the timescale for the released heat to reach the neutron-star photosphere is shorter than for flashes that result from the burning of carbon and other heavier elements. Enhanced CNO abundances ( $N_{CNO} \gtrsim 10^{-2}$ ) are needed if hydrogen-burning flashes are to be sufficiently energetic.

The burning of heavier elements within an accreting neutron star is likely to be thermally unstable under a wide range of conditions<sup>14</sup>. The effects of such instabilities could be more difficult to observe than the X-ray bursts detected, since the radiation may well be emitted at characteristic photon energies considerably less than 10 KeV and on timescales considerably longer than 10 s.

For thermonuclear flashes under nearly all possible circumstances, the value of  $\alpha_{flash}$  will be  $\gtrsim 10$ ; the most plausible values of  $\alpha_{flash}$  are  $\gtrsim 10^2$ . (The smallest values of  $\alpha_{flash}$  will be attained for low-mass neutron stars, with small values of  $\eta_n$ , or for hydrogen-burning flashes involving highly enhanced CNO abundances, with large values of  $\eta_n$ .) Hence, a thermonuclear-flash model cannot account for MXB1730-335 ( $\alpha \lesssim 2$ ) unless one inserts an additional *ad hoc* complication into the model, such as highly anisotropic beaming of the steady emission so that it largely misses the Earth. But, the empirical difference between the behaviour of MXB1730-335 and other burst sources (refs 2, 3 and references therein) suggests that the fundamental nature of this source may be unique. The burst source MXB1659-29, which has recently been found to have  $\alpha < 25$  (W. Lewin, J. Hoffman, and J. Doty, unpublished SAS-3 data), may also pose a serious problem for thermonuclear-flash models.

Another difficulty with thermonuclear-flash models is their prediction of simple blackbody spectra for X-ray bursts, in contrast to the rather complex changes in spectrum that are displayed during the progress of some observed bursts<sup>2,3</sup>. To account for such behaviour, it is necessary to invoke time-dependent reprocessing of the burst radiation by matter above the

Alfvén surface of the neutron star. It is worth noting, however, that the time-averaged burst spectra more closely resemble a blackbody than a thin-bremsstrahlung or power-law spectrum<sup>2</sup>. Moreover, the instantaneous spectra of at least three burst sources seem to be well-represented by a blackbody with an effective radius of  $\sim 10$  km throughout the course of each burst<sup>2,3-25</sup>.

On the other hand, thermonuclear-flash models may provide a natural explanation for the quasi-periodic character of the recurrence intervals that have been observed in several burst sources<sup>2,3</sup>. If the accretion rate on to the neutron star is nearly constant on a timescale of days and each burst consumes about the same amount of fuel, then a nearly constant interval between bursts may result (since a specific envelope mass may be needed to precipitate a flash). The observed variations in the recurrence intervals on timescales of several days to weeks could result from variations in the accretion rate on such timescales, while the cessation of bursting in many sources for periods of months or longer may be caused by either (1) a sharp reduction in the accretion rate or (2) an increase in the accretion rate that changes the properties of the neutron-star surface layers so as to alter the character of the nuclear fusion processes.

It is somewhat puzzling that all accreting neutron stars do not display some evidence of thermonuclear flashes. There are 12 known X-ray pulsars, which are widely believed to be accreting neutron stars (see ref. 22 and references therein) but which have not been observed to burst. It is possible that the X-ray burst sources are intrinsically very similar to the X-ray pulsars, but with lower accretion rates or other differences in system parameters<sup>10</sup>. But, in all cases investigated by Hansen and Van Horn<sup>15</sup>, the nuclear burning shells were either thermally unstable or at most marginally stable. These models do show a slight trend toward greater stability of nuclear burning as the mass accretion rate increases, but instability was found even at accretion rates corresponding to steady X-ray luminosities of as much as  $\sim 10^4 L_\odot$ . A better understanding of these problems must await a detailed time-dependent numerical treatment of nuclear fusion processes in neutron-star surface layers.

As noted above, it is possible that more than one mechanism is responsible for the observed burst sources. In order to distinguish between models invoking massive black holes<sup>1,5,6</sup> and those which involve moderate-mass compact objects<sup>7-12</sup> that may be in binary systems, observations of X-ray pulsing, X-ray eclipses, or optical companion stars which exhibit binary characteristics (ellipsoidal light variations or orbital velocity curves) could prove decisive.

It is equally important and, in principle, more straightforward to distinguish between thermonuclear-flash models for burst sources and those models which involve instabilities in accretion on to a neutron star<sup>7-11</sup>. This could be accomplished by determining the distribution of values of  $\alpha$  for a large statistical sample of sources. If the value of  $\alpha$  for most sources were  $\gtrsim 10^2$ , strong support for thermonuclear-flash models would be provided. If, on the other hand, there exists a relatively continuous distribution of values of  $\alpha$  extending well below  $10^2$ , then one could reasonably conclude that nuclear flash-burning is not responsible for any of the burst sources.

I thank many colleagues, especially Saul Rappaport, for helpful discussions and Professor Martin Rees and the Institute of Astronomy for their hospitality during August 1977. This work was supported in part by NASA (contract NAS5-11450). The author is an Alfred P. Sloan Research Fellow.

# Ovalbumin gene is split in chicken DNA

R. Breathnach, J. L. Mandel & P. Chambon

Laboratoire de Génétique Moléculaire des Eucaryotes du CNRS, Unité 44 de l'INSERM et Institut de Chimie Biologique, Faculté de Médecine, Strasbourg, France

*The ovalbumin gene, is split in chicken DNA. Two interruptions in the sequences coding for ovalbumin mRNA have been detected, at least one of them lying in the protein coding sequence. The unexpected gene organisation is present both in oviduct cells highly specialised in ovalbumin synthesis and in erythrocytes.*

DNA SEQUENCES coding for the variable and constant regions of immunoglobulin molecules are widely separated in embryo cells but are much closer in differentiated lymphocytes<sup>1</sup>. This finding suggests that gene rearrangement could be one of the mechanisms involved in cell differentiation. Chicken oviduct is particularly useful for the study of such a possibility, since administration of oestrogen to immature chicks results in cytodifferentiation of tubular gland cells, which comprise up to 90% of the cells in the magnum portion of laying hen oviduct and which synthesise the major egg white proteins including ovalbumin, ovomucoid, conalbumin and lysozyme (see refs 2, 3). In particular, ovalbumin accounts for 50–65% of total protein synthesis in tubular gland cells, and the rate of transcription of its mRNA (which represents 40% of the total mRNA population) is under hormonal control<sup>3,4</sup>.

As reported for integrated viral genes<sup>5</sup>, it is possible to construct a physical map of restriction endonuclease sites within and around a single-copy gene. Briefly, this involves cleavage of the DNA with various restriction endonucleases, fractionation of the fragments by electrophoresis, their transfer to nitrocellulose sheets<sup>6</sup>, hybridisation to a specific probe labelled *in vitro* by nick-translation<sup>7</sup> to high specific activity and location of the gene fragments by autoradiography. In this study we have used the bacterial plasmid, pCR1ov2.1, which contains about 80% of the nucleotide sequences present in ovalbumin mRNA<sup>8</sup> as a hybridisation probe to investigate the possibility that the ovalbumin gene environment could be different in DNA prepared from laying hen oviduct or erythrocytes. Unexpectedly, we have found that the DNA sequences complementary to ovalbumin mRNA are split into several fragments in oviduct DNA, and that the same peculiar ovalbumin gene organisation is present in laying hen oviduct and erythrocyte DNA.

## Mapping chicken ovalbumin gene in oviduct and erythrocyte DNA

The *HhaI* fragment A (termed *Hhaov*) of the ovalbumin clone pCR1ov2.1 is about 2,400 base pairs long and contains a sequence of about 1,730 base pairs coding for ovalbumin mRNA<sup>8</sup>. After nick-translation with <sup>32</sup>P-labelled deoxyribonucleoside triphosphates<sup>7</sup>, this fragment serves as a filter hybridisation probe to detect DNA fragments containing the ovalbumin gene in restriction endonuclease digests of chicken DNA, using the blotting technique developed by Southern<sup>6</sup>.

**Fig. 1** Detection of ovalbumin gene sequences in chicken DNA cleaved with *EcoRI* or *HindIII*. DNA from the magnum portion of laying hen oviduct or from erythrocyte nuclei was purified as in refs 10 and 11, respectively. DNA samples were digested to completion with the restriction enzymes *EcoRI* or *HindIII* (gifts of Dr J. Sümegi). To monitor the extent of digestion, phage  $\lambda$  DNA was included in the incubations. Some digests were treated with proteinase K, phenol extracted, ethanol precipitated and redigested in the presence of fresh phage  $\lambda$  DNA to ensure complete cleavage. Samples of the digested DNA (10  $\mu$ g) were electrophoresed on 0.7% Agarose gels (17 cm long, 4 mm thick, lane width 8 mm) at 2 V  $\text{cm}^{-1}$ , transferred to nitrocellulose filters (Schleicher and Schell BA85) by a modification of the method of Southern<sup>6</sup>, and fixed to the filter by baking in a vacuum at 80 °C for 3 h. Before hybridisation, filters were soaked at 68 °C in 5  $\times$  SSC, 0.1 M sodium phosphate pH 7.0 containing 0.02% each of Ficoll, bovine serum albumin and polyvinylpyrrolidone<sup>12</sup>. Hybridisation to <sup>32</sup>P-labelled *Hhaov* fragment (0.1  $\mu$ g, 0.5–2  $\times 10^7$  c.p.m.) labelled by nick-translation<sup>7</sup> was carried out in the soaking solution for 16 h at 68 °C (ref. 5). The filters were washed first with the soaking solution containing 0.5% SDS, then extensively with 1  $\times$  SSC, 0.1 M sodium phosphate pH 8.4, containing 0.5% SDS. All washing was done at 68 °C. Autoradiography was for 7 d at room temperature with a Kodirex film (Kodak). *Hhaov* fragment was purified from an *HhaI* digest of pCR1ov2.1 DNA by sedimentation in a 5–20% sucrose gradient. Lane 1, Internal markers for molecular weight and hybridisation were prepared from pCR1ov2.1 DNA by cleavage with various restriction nucleases. Only fragments containing ovalbumin gene sequences are revealed after hybridisation. The molecular weight of the fragments was determined using adenovirus 2 DNA cleaved by *EcoRI* or *BamHI* as standard<sup>14</sup>. The enzymes generating the observed bands and the sizes of the fragments (in kilo base pairs) are: a, *HindIII*, 13.5; b, *SmaI*, 8.3; c, *HindIII/PstI*, 6.5 (contains the sequences present in *PstI*A fragment (see Fig. 2)); d, *HindIII/PstI*, 2.6 (contains sequences present in *PstI*B fragment (see Fig. 2)); e, *HhaI*, 2.4. Lanes 2–5, *EcoRI* digests of erythrocyte (lanes 2, 3) or oviduct (lanes 4, 5) DNA. Samples in lanes 3 and 5 were digested twice (see above). The sizes of the fragments hybridising to *Hhaov* are (in kilo base pairs): a, 9.5; b, 2.35; c, 1.8; d, 1.3. Lanes 6–9, *HindIII* digest of erythrocyte (lanes 6, 7) or oviduct (lanes 8, 9) DNA. Samples in lanes 7 and 9 were digested twice (see above). The sizes of the fragments hybridising to *Hhaov* are (in kilo base pairs): a, 4.9; b, 3.2; c, 2.3.

**Fig. 2** *a*, Physical map of restriction enzyme sites in the *Hhaov* fragment and orientation of the ovalbumin double-stranded cDNA insert (J.L.M., in preparation). Only the sites relevant to the present study are shown (for convenience, restriction endonuclease *HinfI* is termed *Hinf*). The position of the restriction endonuclease sites on the *Hhaov* fragment is given from the 3' end of the mRNA (excluding the poly (A) tail) assuming that the site *HinfI* corresponds to that predicted from the known sequence of ovalbumin mRNA around position 180 from its 3' end<sup>15</sup>. This assumption is supported by the demonstration that the *HinfB* fragment hybridises to mRNA (J.L.M., in preparation). Since the cloned ovalbumin ds cDNA sequence is about 1,730 nucleotides long<sup>8</sup>, all restriction sites from *HinfI* to *Hinf4* inclusive are located in a DNA sequence complementary to ovalbumin mRNA. Location and sizes of all fragments that have been used as hybridisation probes are also shown. *b*, Physical map of relevant restriction endonuclease sites of *in vitro* synthesised ovalbumin ds cDNA as established by Monahan *et al.*<sup>9</sup>. The position of the restriction enzyme sites is given from the 3' end of the mRNA. The two maps are in very good agreement when taking into account that different electrophoresis gel systems and molecular weight markers were used in the two studies.

High molecular weight DNA was prepared from chicken oviduct and erythrocytes, digested with the restriction enzymes *EcoRI* or *HindIII*, electrophoresed on Agarose gels, denatured, and transferred to nitrocellulose filters<sup>6</sup>. After hybridisation with denatured <sup>32</sup>P-labelled *Hhaov* fragment and autoradiography, several bands were seen as shown in Fig. 1, suggesting that sequences complementary to ovalbumin mRNA are present in different DNA fragments. The autoradiography band pattern was identical for oviduct and erythrocyte DNA (Fig. 1) and also for 5-d-old chick embryo DNA (not shown). This multiplicity of hybridisation bands was unexpected, since there is no *EcoRI* or *HindIII* restriction enzyme site in the cloned ovalbumin cDNA sequences (Fig. 2). Absence of such sites in *in vitro* synthesised ovalbumin double-stranded cDNA (ds cDNA) was also recently reported by Monahan *et al.*<sup>9</sup>. The very good agreement between the restriction maps of the cloned and *in vitro* synthesised ds cDNAs (Fig. 2), together with our previous results<sup>8</sup>, exclude the possibility that the multiplicity of the bands can be attributed to DNA sequence rearrangements which might have occurred during the cloning and/or amplification of the ds cDNA. The following results exclude the possibility that the multiple hybridisation bands could be related to incomplete restriction enzyme digestion of the chicken DNA or to nonspecific hybridisation: (1) there was no change in the pattern when the DNA was digested twice, while the phage  $\lambda$  DNA internal marker was digested each time to completion (Fig. 1); (2) the hybrid bands were present even in much more stringent washing conditions (0.1 SSC, 0.5% sodium dodecylsulphate, 68 °C) and were as stable as the hybrids formed with the internal hybridisation markers (see legend to Fig. 1); (3) no hybridisation bands were observed when *EcoRI* DNA fragments of high molecular weight calf thymus DNA were used instead of *EcoRI* DNA fragments of high molecular weight calf thymus DNA were used instead of *EcoRI* fragments of chicken DNA (not shown); (4) the same bands were observed when the *Hhaov* probe was replaced by a probe from which plasmid sequences and GC tails adjacent to the ovalbumin sequences were removed by hy-

bridisation with ovalbumin mRNA followed by S1 nuclease treatment, as described in the legend to Fig. 4.

### Hybridisation to probes complementary to defined parts of ovalbumin mRNA

To investigate the significance of the multiple hybridisation bands we have prepared the <sup>32</sup>P-labelled fragments *PstA*, *PstB* and *HinfA* (see legend to Fig. 3). As illustrated in Fig. 2, the *PstA* probe contains most of the DNA sequences complementary to the first 1,420 nucleotides of the mRNA, starting from its 3' end. The *PstB* probe contains DNA sequences complementary to the 5' region of the mRNA from positions 1,420 to at least 1,630 from the 3' end of the mRNA. The *HinfA* probe contains only sequences complementary to the central part of the mRNA (Fig. 2). The hybridisation patterns of <sup>32</sup>P-labelled *PstA* and *PstB* probes to *EcoRI* or *HindIII* restriction fragments of oviduct DNA are shown in Fig. 3. The *PstA* probe hybridised with *EcoRI* fragments a, c and d, but not with fragment b (lane 3). The *HinfA* probe gave results very similar to those obtained with the *PstA* probe (not shown). On the other hand, the *PstB* probe hybridised strongly to the *EcoRI* fragment b, and only weakly to the *EcoRI* fragment a (lane 7). A similar pattern was found with *HindIII* fragments, since the *HindIII* fragment b did not hybridise with *PstA* (lane 4) or *HinfA* (not shown) probes, whereas it was responsible for the main band with the *PstB* probe (lane 8); this latter probe hybridised only weakly to *HindIII* fragment a. But, the *PstB* probe seemed to be contaminated with *PstA* sequences. Annealing of the *PstB* probe to the pCR10v2.1 fragments serving as internal markers showed indeed that it hybridised with both fragments c and d (Fig. 3, lane 5), which contain the *PstA* and the *PstB* DNA sequences respectively (J. L. Mandel, in preparation and legend to Fig. 1). On the other hand, the *PstA* probe hybridised only to the internal marker fragment c and not to the

**Fig. 3** Detection of fragments containing sequences complementary to defined parts of ovalbumin mRNA in digests of chicken oviduct DNA with *EcoRI*, *HindIII* or *PstI*. DNA samples were prepared as described in Fig. 1, except that SV40 DNA was used to monitor the digestions with *PstI* (Biolabs). *PstA* and *PstB* probes were labelled by nick-translation of a *PstI* digest of *Hhaov*. After electrophoresis on a 2% agarose gel, the labelled *PstA* and *PstB* fragments were extracted from the gel<sup>16</sup>. Their specific activity was about  $1 \times 10^8$  c.p.m.  $\mu\text{g}^{-1}$ . Autoradiography was carried out with 'pre-flashed' Kodak RP Royal X-Omat film and intensifying screen at  $-70^\circ\text{C}$  for 7 d. All other procedures were as described in Fig. 1. Lanes 1-4, hybridisation to  $^{32}\text{P}$ -*PstA*. Lanes 5-8, hybridisation to *PstB*; lanes 1 and 5, internal markers (see Fig. 1). Lanes 2 and 6, *PstI* digest of chicken DNA—sizes of the fragments in kilo base pairs; a, 4.7; b, 2.2. Lanes 3 and 7, *EcoRI* digest of chicken DNA (see Fig. 1 for fragment sizes). Lanes 4 and 8, *HindIII* digest of chicken DNA (see Fig. 1 for fragment sizes).

marker fragment d (Fig. 3, lane 1). This indicates that the *PstA* probe did not contain sequences complementary to *PstB*, and that the hybridisation of the *PstB* probe to the marker fragment c was due to a contamination of that probe. This contamination could be due to some degradation of the *PstA* fragment during  $^{32}\text{P}$ -labelling, since the two probes were separated by gel electrophoresis after the nick translation reaction (see legend to Fig. 3). In any case, assuming that the weak hybridisation of the *PstB* probe to the *EcoRI* and *HindIII* fragments 'a' were due to such a contamination, our results with probes *PstA* and *PstB* suggested the possibility that, in the cellular DNA, some sequences complementary to the 5' moiety of the ovalbumin mRNA are physically separated from those complementary to the rest of the mRNA.

### Confirmation that the chicken ovalbumin gene is split

DNA fragments from *EcoRI*/*HindIII*, *EcoRI*/*PstI* and *HindIII*/*PstI* double digests were hybridised to  $^{32}\text{P}$ -labelled probes complementary to different regions of the ovalbumin mRNA (Fig. 4). As expected, multiple hybridisation bands were revealed by autoradiography. Their pattern was identical for oviduct and erythrocyte DNA (data not shown). Irrespective of the combination of restriction endonucleases, there was always one DNA fragment which hybridised strongly to *PstB*, but not to

*PstA* or *HinfA*: band 'b' for the *EcoRI*/*HindIII* digest (compare lanes 1, 4, 6, 8) and for the *HindIII*/*PstI* digest (lane 3, hybridisation with *PstA*, *PstB* and *HinfA* probes are not shown), band 'c' for the *EcoRI*/*PstI* digest (compare lanes 2, 5, 7 and 9). From the hybridisation pattern with *PstA* and *HinfA*, it is clear that fragments 'a' of *EcoRI*/*HindIII* and *EcoRI*/*PstI* double digests contain most of the ovalbumin sequences located to the left of the *PstI* site (see the map in Fig. 2a). But, when the lengths of these 'a' fragments were compared, a striking anomaly became apparent. The *EcoRI*/*HindIII* fragment was shorter than the *EcoRI*/*PstI* fragment by about 150 base pairs (2,600 and 2,750 base pairs, respectively). This shorter length cannot be attributed to a contaminating exonuclease activity in the *HindIII* enzyme, since all the restriction endonucleases used in this study were shown to be free of exonuclease activity even after prolonged incubations. Since the DNA fragment of an *EcoRI* digest which hybridises strongly to *PstA* or *HinfA* probes is 9,500 base pairs (Fig. 3, fragment 'a', lane 3), it follows that the *EcoRI*/*HindIII* and *EcoRI*/*PstI* fragment 'a' must share the same *EcoRI* terminus. There is therefore a *HindIII* site in the chromosomal *EcoRI*/*PstI* fragment 'a' at 150 base pairs from the *PstI* terminus. But, no *HindIII* site has been found in the cloned ovalbumin ds cDNA or in the *in vitro* synthesised ds cDNA (see above and Fig. 2). One has therefore to conclude that the *PstI* site present at one terminus of the DNA fragment 'a' of an *EcoRI*/*PstI* double digest is not identical to the *PstI* site present in the cloned or *in vitro* synthesised ds cDNA (Fig. 2). The simplest explanation to account for these results is that the DNA sequences complementary to the probes *PstA* (or *HinfA*) and *PstB* (Fig. 2) are physically separated, and that the DNA sequence coding for the

**Fig. 4** Detection of fragments containing sequences complementary to defined parts of ovalbumin mRNA in chicken DNA cleaved with a combination of restriction enzymes. Electrophoresis was on a 1% agarose gel.  $^{32}\text{P}$ -labelled fragments of *Hhaov* were prepared by the method described in Fig. 3. To obtain probes containing only sequences complementary to ovalbumin mRNA, labelled *Hhaov*, *PstA* and *PstB* were annealed to a 10-fold excess of ovalbumin mRNA at  $50.5^\circ\text{C}$  in 100 mM PIPES buffer, pH 7.9, containing 70% formamide, 100 mM NaCl, 10 mM EDTA (after denaturation at  $80^\circ\text{C}$  in this buffer). DNA-DNA hybrids are not stable in these conditions<sup>17</sup>. Single-stranded plasmid sequences and GC tails were digested with S1 nuclease (Miles). The RNA-DNA hybrid was precipitated with ethanol and then treated with RNase A in 10 mM Tris-HCl pH 8.0, 1 mM EDTA at  $50^\circ\text{C}$  to generate single-stranded probes. All other methods were as described in Fig. 3. Filters were hybridised to single-stranded *Hhaov* (lanes 1-3), single-stranded *PstA* (lanes 4 and 5), single-stranded *PstB* (lanes 6 and 7) or to *HinfA* (lanes 8 and 9). Lanes 1, 4, 6, 8, *EcoRI*/*HindIII* double digest of chicken DNA—sizes of the fragments are, in kilo base pairs: a, 2.6; b, 2.05; c, 1.8; d, 1.3. Lanes 2, 5, 7, 9, *EcoRI*/*PstI* double digest of chicken DNA—sizes of the fragments are in kilo base pairs: a, 2.75; b, 2.15; c, 1.9; d, 1.65; e, 1.3. Lane 3, *HindIII*/*PstI* double digest of chicken DNA—sizes in kilo base pairs: a, 4.4; b, 3.1; c, 1.5; d, 1.3. Fragment b does not hybridise to *PstA* or *HinfA*, but represents the main band with the *PstB* probe (not shown).

**Fig. 5** Detection of ovalbumin gene sequences in chicken DNA cleaved with *HinfI* and *HinfI* plus *HaeIII* restriction nucleases. Chicken DNA was digested with endonuclease *HinfI* (gift of Dr D. Duck) or *HaeIII* (Biolabs), with SV40 DNA as internal marker, and electrophoresed on a 1.5% Agarose gel. All other procedures were as described in Fig. 3. Autoradiography was for 3 d. Filters were hybridised to either  $^{32}\text{P}$ -Hhaov fragment,  $10^8$  c.p.m.  $\mu\text{g}^{-1}$  (lanes 1 and 2) or to  $^{32}\text{P}$ -HinfA fragment  $6 \times 10^7$  c.p.m.  $\mu\text{g}^{-1}$  (lanes 3–9). Lanes 1, 3 and 5, internal markers. Bands d and e are described in the legend to Fig. 1. Bands f and g correspond to the *HinfA* and *HinfB* fragments of Hhaov, 880 and 750 base pairs long, respectively (Fig. 2). Lanes 2, 4 and 6, chicken DNA digested with *HinfI*—sizes of the fragments in base pairs: a, 1,300; b, 800. Lane 7, chicken DNA digested with *HinfI* and *HaeIII*—size of band a, 800 base pairs. Lanes 8 and 9, internal markers; band e, see Fig. 1. fragment h, obtained by double digestion of Hhaov with *HaeIII* and *HinfI*, corresponds to the 650 base pair fragment between the *Hinf2* and *HaeIII* sites of the ds cDNA (see Fig. 2).

3'moiety of the mRNA (complementary to *PstA* and *HinfA*) is linked to a DNA sequence not coding for ovalbumin mRNA and containing a *HindIII* and a *PstI* site 150 base pairs apart.

Further evidence supporting the existence of a split ovalbumin gene was provided by the results of digestion of chicken DNA with *HinfI* endonuclease. As shown in Fig. 2, *HinfI* cuts the double-stranded DNA sequence complementary to ovalbumin mRNA in four places. One centrally located fragment, *HinfA*, is 880 base pairs long. This fragment should be found in a *HinfI* digest of chicken oviduct DNA, if the ovalbumin gene were not split in that region. Figure 5 shows the hybridisation pattern of the *HinfI* oviduct DNA fragments to  $^{32}\text{P}$ -labelled Hhaov and *HinfA* probes. The Hhaov probe hybridised mainly to two DNA fragments, 800 and 1,300 base pairs (Fig. 5, lane 2), while *HinfA* hybridised only to the 800-base pair DNA fragment (Fig. 5, lanes 4 and 6). The use of a *HinfI* digest of the Hhaov fragment (Fig. 5, lanes 1, 3 and 5) as an internal marker for hybridisation and molecular weight determination demonstrates unambiguously that the 80-base pair difference between the length of the *HinfA* fragment and that of its chromosomal DNA counterpart is real. In addition, the 800-base pair chicken DNA *HinfI* fragment which hybridises to the *HinfA* probe was not cut by *HaeIII* restriction endonuclease as shown in Fig. 5, lane 7, where a *HaeIII*/*HinfI* double digest of chicken DNA was electrophoresed. The implication of these results is that there is an interruption in the chromosomal DNA sequence coding for ovalbumin mRNA between the *Hinf2* and *HaeIII* sites of the ds cDNA (see Fig. 2).

## The ovalbumin gene is split in the coding region irrespective of the differentiated state of the cell

The data presented above show that in the chicken genome the DNA sequences coding for ovalbumin mRNA are split between the *Hinf2* and the *HaeIII* sites present in the ds cDNA. If the genomic DNA sequences coding for the remaining 5' part of the ovalbumin mRNA were in one piece one would expect that the *PstA* probe would hybridise to the same *EcoRI* or *HindIII* chicken DNA fragments which hybridise to the *PstB* probe, as these fragments would carry at least 320 bp also present in the *PstA* probe. As shown in Fig. 3, this was clearly not the case: the *EcoRI* and *HindIII* fragments 'b' which hybridised to the *PstB* probe did not hybridise to the *PstA* probe (Fig. 3). In consequence the genomic DNA sequences coding for ovalbumin mRNA must be split a second time near the *PstI* site of the ovalbumin ds cDNA (Fig. 2). The approximate location of the interruptions of the DNA sequences coding for ovalbumin mRNA are shown schematically in Fig. 6a, with respect to the restriction endonuclease sites present in the cloned ovalbumin ds cDNA (Fig. 2). Preliminary results suggest that the site of the first interruption lies close to the *HaeIII* restriction site. In any case at least one of the interruptions is located in a region coding for the ovalbumin protein: 1,161 nucleotides are required to code for the 387 amino acids of hen ovalbumin<sup>18</sup>, and it was recently shown that the first 250 nucleotides from the 3' end of the mRNA do not code for the protein<sup>15</sup>.

The occurrence of two interruptions could account for the origin of three of the fragments hybridising to the ovalbumin probe in an *EcoRI* digest of chicken DNA. The existence of a fourth band (Fig. 1) might suggest the presence of a third interruption.

Figure 6b and c show the map of the restriction endonuclease sites flanking regions I and III, which code for RNA sequences present in the 3' and in the 5' regions of the ovalbumin messenger, respectively. These maps were established from the lengths of the main fragments hybridising to the *PstA* and *PstB* probes (Figs 1, 3 and 4). We do not yet know the orientation of transcription of the ovalbumin RNA sequences. Comparison of these maps indicates that the DNA sequences surrounding region III (Fig. 6c) cannot be included in the 12,000-base pair DNA fragment containing region I (Fig. 6). Depending on the orientation of transcription, region I is separated in the genome from region III by either at least 2,500 base pair or at least 7,500 base pair (see Fig. 6b).

Our hybridisation studies do not reveal any DNA fragment which could be derived from an uninterrupted 'intact' ovalbumin gene. In addition we have no evidence for major variations in the structural organisation of the split gene. Since 80% of the laying hen oviduct cells are actively engaged in ovalbumin mRNA synthesis<sup>3,4</sup> and since there is evidence that ovalbumin genes are present at approximately one copy per haploid genome (see ref. 3), we conclude that ovalbumin mRNA is transcribed from split genes. The oviduct DNA used in this study was isolated from total oviduct and it is therefore unlikely that loss of possible extrachromosomal elements carrying an 'intact' ovalbumin gene could have occurred. This peculiar arrangement of the genomic DNA coding for ovalbumin mRNA is apparently unrelated to the highly differentiated state of laying hen oviduct tubular cells. In all cases studied, the hybridisation patterns were identical for restriction digests of oviduct, erythrocyte or 5-d old embryo DNAs, indicating that there is no major modification of the ovalbumin gene organisation and environment during the differentiation of cells highly specialised in ovalbumin synthesis.

## Conclusions

It is not known how the different DNA regions of the split ovalbumin gene are organised in chicken DNA. There are two types of model that would be consistent with our results. In the first type of model, the insertion model, the different regions I, II and III (Fig. 6a) are all on the same DNA segment in the same order and orientation as in the *in vitro* synthesised ds cDNA, but they are separated by DNA sequences (insertions) that are not represented in mature mRNA. In the second type of model, the

**Fig. 6** Organisation of the sequences coding for ovalbumin mRNA in cellular DNA. *a*, Interruptions in the genomic ovalbumin DNA sequences. The arrows indicate the approximate location of the two interruptions and define three different regions (I, II and III) coding for ovalbumin mRNA. *b* and *c*, Physical map of restriction endonuclease cleavage sites flanking regions I and III, respectively. The dashed lines represent the DNA segments containing regions I or III. The sizes of the fragments used to establish these maps are (in kilo base pairs, see also Figs 1, 3 and 4) for region I: *EcoRI*, 9.5; *HindIII*, 4.9; *PstI*, 4.7; *EcoRI/HindIII*, 2.6; *EcoRI/PstI*, 2.75; *HindIII/PstI*, 4.4; for region III: *EcoRI*, 2.35; *HindIII*, 3.2; *PstI*, 4.7; *EcoRI/HindIII*, 2.05; *EcoRI/PstI*, 1.9; *HindIII/PstI*, 3.1. In each case the map was constructed using the first five values. From these maps one can predict sizes for the *HindIII/PstI* fragments which are in very good agreement with those found experimentally.

different regions are not in the same order and orientation as in the ds cDNA and could even be on different chromosomes. Further mapping of the ovalbumin sequences in chicken DNA is in progress, in the hope of finding a fragment which will contain all three regions of the ovalbumin gene, thereby supporting the insertion model. Up to now, no such fragment has been found. This does not rule out the insertion model, since the chance of finding such a fragment decreases with the length of the insertion.

The existence of DNA insertions within eukaryotic genes has recently been demonstrated for 28S ribosomal cistrons of *Drosophila melanogaster*<sup>19-22</sup>. But, since intact *Drosophila* ribosomal cistrons were also found, the physiological relevance of the insertion could be questioned. A 93-base pair insertion was detected and sequenced in the 5' region of the protein coding sequence of a cloned immunoglobulin variable gene of mouse embryo (S. Tonegawa, personal communication), and a 1,250-base pair insertion was found within the coding sequence of a cloned mouse plasmacytoma  $\lambda$  chain DNA, separating the sequences coding for the variable and constant regions of the  $\lambda$  chain (C. Brack & S. Tonegawa, personal communication). Using an approach very similar to ours, which eliminates the possible complications related to accidental selection of defective genes and/or DNA rearrangements during cloning, A. Jeffreys and R. Flavell (*Cell*, in the press) have detected the presence of a 600-base pair insertion within the protein sequence of the rabbit  $\beta$ -globin gene. A similar insertion was found in a cloned mouse  $\beta$ -globin gene (P. Leder, personal communication). It seems therefore that the splitting of genes within the protein coding sequence may have some generality in eukaryotic cells.

It is too early to speculate on the role of the split gene organisation in the regulation of gene expression at the transcriptional and/or post-transcriptional levels. But, the two types of model discussed above for the ovalbumin gene lead to different predictions concerning the general processes by which a split gene could be transcribed to give a single continuous mRNA. In the case of the insertion model three possible mechanisms already proposed to account for the mosaic late adenovirus mRNAs<sup>23-25</sup> could apply to the ovalbumin gene: (1) RNA polymerase B which is responsible for ovalbumin mRNA synthesis<sup>4</sup> could jump with the attached nascent RNA across looped out insertions, transcribing in an ordered fashion the ovalbumin gene regions III, II

and I (Fig. 6a) to yield directly the mRNA; (2) both insertions and messenger coding regions could be transcribed resulting in an ovalbumin mRNA precursor. The mature mRNA could then be formed by excision of the insertion transcripts and splicing of the mRNA sequences. The size of the precursor should be at least twice that of mature ovalbumin mRNA, since the minimum distance separating regions I and III in the insertion model is about 2,500 base pairs (see above and Fig. 6); (3) each of the mRNA coding segments may be transcribed independently and the ovalbumin mRNA generated by ligation of the transcripts. This latter mechanism, but not the two former ones, could also apply to the second type of model of the split gene where the mRNA coding regions are not placed in an ordered fashion (see above). We have no direct evidence to distinguish between these three possibilities, since the previous failure to detect an ovalbumin mRNA precursor<sup>26</sup> must be reinvestigated in the light of the recent finding concerning the short half-life of the  $\beta$ -globin mRNA precursor<sup>27,28</sup>.

The split gene type of organisation poses additional problems for studying *in vitro* the mechanisms involved in the specificity of transcription. The phenomenon of split genes in eukaryotic cells also diminishes the chance of obtaining single clones containing the DNA sequences coding for the entire mRNA and its putative regulatory elements. Furthermore, even where such clones may be isolated, it is unlikely that they could be used for the expression of eukaryotic genes in bacteria, as the necessary machinery for post-transcriptional processing may well not be present in prokaryotic organisms. Progress in this field may have to be based on the linking of known bacterial regulatory elements to ds cDNA clones containing the entire protein coding sequence.

We thank J. Sümegi, J. P. LePennec and A. Krust for generous gifts of materials, and M. C. Chanal for technical assistance. This work was supported by grants from INSERM (CRT 76.5.468 and 76.5.462), CNRS (ATP 2117) and the Fondation pour la Recherche Médicale Française. R. Breathnach was supported by a long-term EMBO fellowship.

# letters to nature

## Low energy $\gamma$ -ray observation of NGC4151

OBSERVATIONS of the Seyfert galaxy NGC4151 by Ariel V, OSO VII and UCSD (refs 1-3 respectively) have demonstrated that it has a relatively flat X-ray spectrum up to photon energies greater than 100 keV. The X-ray luminosity of this object is of the order of  $4 \times 10^{43}$  erg s $^{-1}$  if a distance of 20 Mpc is assumed, and exceeds the integrated luminosity at all the other observed greater wavelengths. Long-term observations<sup>4</sup> by Ariel V indicate that the X-ray emission may originate from a compact object with dimensions less than  $8 \times 10^{15}$  cm, presumably the nucleus of the Galaxy. Here we present the preliminary results of a positive measurement in the low energy  $\gamma$ -ray region of the spectrum, which are in good agreement with the X-ray data

and confirm the intense high energy luminosity of the object.

The Seyfert galaxy NGC4151 was one of the celestial objects observed during a recent balloon flight, from Palestine Texas on 22 and 23 May 1977, of the MISO low energy (0.2-20 MeV)  $\gamma$ -ray telescope<sup>5,6</sup>. The instrument is a semiactively-shielded Compton coincidence system having a sensitive area of about 500 cm $^2$  and an aperture of  $3^\circ \times 20^\circ$  FWHM. The gondola was steered by an orientation system designed to point the telescope in both zenithal and azimuthal planes. A hard X-ray telescope operating in the 30-250 keV energy range was also incorporated in the scientific payload. This detector viewed the same region of the sky as the  $\gamma$ -ray device, with an aperture of  $2^\circ \times 5^\circ$  FWHM and was designed around a sodium iodide crystal 3 mm thick and having a sensitive area of about 70 cm $^2$ .

The entire observation of NGC4151 was made within  $18^\circ$  of the zenith at a floating altitude of about 7 mbar over a period of 3 h. Half of this time was used to obtain the background evaluation. NGC4151 was detected at the  $6.5\sigma$  level (based on the errors of the differences of the on and off source counting rate) in the 0.15-20 MeV energy band. In this preliminary analysis only real time counting rate data, processed by an on-line computer, from the sodium iodide crystal (component of the Compton coincidence system) were used. No spectral information is available at this stage. The observed counting rates after background subtraction at the same zenith angle were corrected for any changes in float altitude. No significant variation in background counting rate with azimuthal angle was observed.

Four transits of the source through the fine aperture of the telescope collimator were performed and a positive increase in  $\gamma$ -ray events observed in each case. The excess photon counting rate of  $8.4 \pm 1.3$  counts s $^{-1}$  at  $\gamma$ -ray energies and  $0.31 \pm 0.23$  counts s $^{-1}$  at X-ray wavelengths has been interpreted as a continuation of the previously measured hard X-ray spectrum. The  $\gamma$ -ray excess has been converted to a photon spectrum at the top of the atmosphere using conversion factors calculated for an input spectral index  $-1$ .

The  $\gamma$  flux obtained in this way is shown in Fig. 1 together with relevant soft and hard X-ray data. The hatched area takes into account both the uncertainties derived from statistical fluctuations at  $1\sigma$  level and the lack of knowledge of the precise exposure of the source. This latter uncertainty is caused by not having continuously updated orientation data in the quick-look mode to better than  $1^\circ$ .

The  $\gamma$ -ray results show good agreement with a power law extension of the X-ray data using a spectral index similar

**Fig. 1** The soft and hard X-ray measurements of NGC4151 compared with the MISO X and  $\gamma$  measurements. The integral  $\gamma$ -ray counting rate has been converted into a differential spectrum (hatched area) using a spectral index  $-1$ .

to that suggested by Baity *et al.*<sup>2</sup>. The extension of the emission spectrum of NGC 4151 up to 20 MeV would correspond to a luminosity of  $(8 \pm 2) \times 10^{45}$  erg s<sup>-1</sup> for a distance of 20 Mpc.

## Optical candidates for two X-ray bursters and an X-ray pulsar

WE suggest faint ( $B \sim 18$ ), blue stars as the optical counterparts of two X-ray bursters, 4U1636–53 (MXB1636–53)<sup>1–4</sup> and 4U1735–44 (MXB1735–44; KGX345–67)<sup>1,4–6</sup>, and for the 7-s X-ray pulsar, 4U1626–67<sup>1,7,8</sup>. The candidate stars have large ultraviolet excesses and were discovered well within the 20" and 30" X-ray error radii determined using the rotating modulation collimator experiment aboard the SAS-3 X-ray Observatory<sup>9,10</sup>. Photographic observations of several X-ray error boxes were performed (by C.R.C. and W.A.H.) in April 1976 (before final SAS-3 X-ray positions were known) with the 4-m telescope at the Cerro Tololo Interamerican Observatory (CTIO).  $R$ ,  $B$  and  $U$  plates were obtained for the regions including 4U1636–53 and 4U1735–44. The  $R$  plates (RG610 filter with 127-04 emulsion) are shown as

finding charts in ref. 9. Preliminary iris photometry of some of the plates was performed to identify the bluest stars in each error box for further study.

The photoelectric photometry was performed (by J.E.M.) using the 1.5-m telescope at CTIO during 8–13 June, 1977. A 10" aperture, a standard  $UBV$  filter set and an RCA 4516 photomultiplier tube were used during the entire run. For each colour typical integration times were 10 s for standard stars and 50 s for the programme stars and sky background. All objects were observed in the colour sequence  $BVUB$  as a check on sky conditions, telescope tracking and the stability of the instrumentation. The observations were made between the fourth quarter and new moon. The sky conditions were of photometric quality throughout each night with the exception of 9 June, which had some cirrus. Five or six  $UBV$  standard stars<sup>11</sup> were observed several times each night. A television guider, mounted at the customary position of the offset-guider eyepiece, was used on four nights (8, 9, 12 and 13 June), and provided the crucial capability to centre stars as faint as  $B \sim 20$  in the photometer aperture.

About 100 faint ( $B \sim 15$ –20) stars in the fields of 16 X-ray sources were examined during the six nights. Most of the observations were made within the 20–30" radius error circles determined using SAS-3 data. Stars with large ultraviolet excesses were discovered in the fields of three X-ray sources: 4U1626–67, 4U1636–53 and 4U1735–44.

A summary of the photometry data, coordinates of the stars and references to literature containing finding charts are given in Table 1. A measurement of the candidate for 4U1626–67 made while setting up on 12 June (0553 UT) and not included in Table 1 indicates that the star may be variable on timescales of minutes, but further observations are necessary to establish this. The three measurements of the candidate for 4U1735–44 show no evidence of variability during the course of four nights. Iris photometry of two  $R$  plates taken four days apart in April 1976 also shows no variability. A spectrogram of this candidate obtained by Bond<sup>12</sup> shows a generally featureless blue continuum with weak  $H\beta$  emission.  $\text{HeII } \lambda 4,686$  and  $\text{HeI } \lambda 5,875$  may also be present weakly in emission.

Figure 1 is a colour-colour diagram showing the measured locations of the candidate stars and several established optical counterparts (see refs 13–17), and the calculated location of a model accretion disk around a massive black hole<sup>18</sup>. The candidates for 4U1626–67 and 4U1636–53 lie further from the reddened supergiant or main sequence than any known counterparts and have colours inconsistent with those of a reddened, normal star. The candidate for 4U1735–44 has the colours of Sco X-1 as well as the colours of a late O or B0 star suffering  $\sim 1$  mag of extinction.

Table 1 Description of optical candidates

X-ray source	Star no.*	Star position ( $\pm 3''$ )		UT (June 1977)	$V^\dagger$	$B-V^\dagger$	$U-B^\dagger$
		RA (1950) ( $h^m, s^s$ )	Dec. (1950)				
4U1626–67 (2S1627–673)	4	16h27m14.2s (321.8–13.1)	–67°21'16"	12d06h05m	18.67	+0.00	–1.18
				12 06 34	18.42	+0.26	–1.23
4U1636–53 (2S1636–536)	3	16 36 56.2 (332.9–4.8)	–53°39'15"	12 03 21	17.52	+0.69	–0.70
4U1735–44 (2S1735–444)	5	17 35 19.0 (346.1–7.0)	–44°25'19"	09 06 39	17.43	+0.24	–0.78
				11 05 10 13 06 54	17.40 17.52	+0.22 +0.21	–0.86 –0.81

\*Finding charts showing the SAS-3 (2S) positions and labelled with these star numbers are given for 4U1626–67 (in ref. 10) and for 4U1636–53 and 4U1735–44 (in ref. 9).

†Uncertainties ( $\sim 90\%$  confidence) in  $V$ ,  $B-V$  and  $U-B$  are  $\pm 0.15$  mag. for 4U1626–67 and  $\pm 0.10$  mag. for 4U1636–53 and 4U1735–44. Uncertainties due to counting statistics are  $\lesssim \pm 0.05$  mag.

The candidates for 4U1735-44 and 4U1636-53 bring the number of possible stellar counterparts to X-ray burst sources to three (the third is Davidson's candidate for Ser X-1<sup>19,20</sup>). The colours of the two presented here are far from those estimated by Katz<sup>18</sup> for an accretion disk surrounding a massive black hole. Evidence of the binary nature of any or all these candidates could resolve the uncertainty over the nature of the bursters (see refs 21, 22). The extreme colours of the candidate for 4U1626-67 are remarkable since this source is a rapid X-ray pulsar<sup>8</sup>. The optical emission of all other X-ray pulsars, with the exception of HZ Her, is dominated by that of the OB companion.

**Fig. 1** A colour-colour diagram in the  $UBV$  system showing the three candidates presented in this paper, several well-established optical counterparts<sup>13-17</sup> and a model accretion disk surrounding a massive black hole<sup>18</sup>. The solid curves give the locus of colours for unreddened, main-sequence stars (V) and supergiants (I) following Davis.<sup>24</sup> The dashed curve is the reddening line for a B0 supergiant.

Possibly 4U1626-67 is an even more extreme example of the HZ Her phenomenon, in which the optical luminosity at maximum light is a direct result of the X-ray emission (see ref. 23).

We thank G. Clark, E. Ng, R. Kelly and other members of the SAS-3 group, E. Cosgrave and the staff at CTIO, and M. Liller, R. McCrosky, C. Shao and the Harvard College Observatory for use of their iris photometer and astrometry machine. This work was supported in part by NASA (grant NGR 23-005-465, Contract NAS-5-11450) and by MIT. J.E.M., C.R.C. and W.A.H. are visiting astronomers, Cerro Tololo Inter-American Observatory, which is operated by the Association of Universities for Research in Astronomy, Inc., under contract with the USNSF.

## Positions of three X-ray burst sources

PRECISE (20-30'') positions of three steady X-ray sources which have been identified recently as X-ray burst sources 4U1636-53 = MXB1636-53 (refs 1, 2), 4U1728-33 = MXB1728-34 (refs 3, 4), and 4U1735-44 = MXB1735-44 (refs 5, 6, 7) are reported here. These positions, hereafter designated with a 2S prefix, have been derived from data obtained with the SAS-3 rotating modulation collimators during a survey of the galactic plane<sup>8-10</sup>. The small solid angles of the error regions make possible a thorough survey of all potential optical, infrared, and radio counterparts of these burst sources. Two of these positions, 2S1636-536 and 2S1735-444, have led to the probable identifications of optical counterparts<sup>11</sup>.

The burst sources MXB1636-53 and MXB1728-34 were discovered respectively with the OSO-8 (ref. 1) and SAS-3 (refs 3, 12) satellites. The source MXB1735-44, located precisely<sup>5</sup> with SAS-3, is probably the burst source KGX345-6 that was discovered earlier<sup>6,7</sup> with the COSMOS 428 satellite. All three sources emit X-ray bursts with peak flux densities (2-15 keV) comparable to, or greater than, that of the Crab nebula and with rise times of 1-2 s.

The association of the X-ray burst sources with the previously known Uhuru sources is now well established (Fig. 1). These identifications have been made possible through the determination<sup>2,3,5</sup> of the burst source positions to an accuracy of 6-10' with the SAS-3 slat collimators<sup>13</sup>. Positions of the steady components of these sources have been measured with the Uhuru<sup>14</sup>, Copernicus<sup>15</sup>, and Ariel V<sup>16</sup> satellites. The present SAS-3 positions are shown in Figs 1 and 2 and Table 1. Astrometric positions and stellar magnitudes are given in Table 2.

An optical study based upon the Copernicus position for MXB1636-53 led to the suggested optical identification<sup>17</sup> of a flare star (star M in Fig. 2) that lies outside but near the 2S error region. A recent study of the 2S1636-536 and 2S1735-444 positions led to the discovery<sup>11</sup> of two faint  $V \sim 17.5$ , ultraviolet excess stars that lie well within the 2S regions (stars 3 and 5 respectively in Fig. 2). A search<sup>18</sup> for an optical counterpart for MXB1728-34 has yielded no likely candidates. Several bright ( $K < 10$  mag) infrared sources have been detected, however, within  $\sim 1'$  of 2S1728-337 by I. Glass and by S. Kleinmann (personal communications).

Altogether, we have measured with SAS-3 precise (20-35'') positions of six steady X-ray sources (other than known globular clusters) which have been identified<sup>1-7,13,19-22</sup> as

**Fig. 1** The burst source locations (dashed lines) and steady source locations (solid lines) MXB1636-53; MXB1728-34 and MXB1735-44. The burst source locations designated MXB, were obtained with the SAS-3 slit collimators (refs 2, 3, 5 and J. Hoffman, personal communication). The steady source locations are from the Uhuru 4U catalogue (U, ref. 14), the Ariel V rotating modulation collimator (A, ref. 16), the Copernicus satellite (C, ref. 15), and the SAS-3 rotating modulation collimator [S (dark circles) present work].

counterparts of X-ray bursters. Previously we reported<sup>9</sup> the positions of Ser X-1 (2S1837+049), A1905+00 (2S1905+000), and 4U1915-05 (2S1916-053). All six lie within 40° of the galactic centre and within 10° of the galactic plane. The intensities of the steady sources measured with SAS-3 agree roughly with those reported previously<sup>14,23</sup>. None of these sources is known to exhibit periodicities, eclipses, or rapid variability other than bursts. These featureless characteristics are typical of the X-ray sources which are located in the galactic bulge. We also note that the burst sources exhibit a galactic distribution<sup>24</sup> similar to the bulge sources.

The bulge X-ray sources are similar to the ~ 6 steady X-ray sources which are identified<sup>23,25-27</sup> with globular clusters, in

that they exhibit a deficiency of hard X rays and are associated with late-type stars in regions of high stellar density<sup>28,29</sup>. Four globular clusters, NGC6624 (ref. 30), NGC1851 (refs 31, 32), NGC6441 (ref. 33) and Liller 1 (refs 34, 35) are now believed to be X-ray bursters. The physical significance of these apparent similarities among burst sources, the bulge sources, and globular cluster sources is not well understood (see ref. 29). This makes the search for and study of optical, infrared, and radio counterparts of the burst sources particularly compelling.

We acknowledge the support of the staffs of the Center for Space Research at MIT and the Goddard Space Flight Center of NASA. We thank C. Canizares, R. Dower, J. Kulik, W. Lewin, and C. Reid for helpful conversations and assistance.

**Fig. 2** Finding charts for the SAS-3 positions. The charts for 2S1636-536 and 2S1735-444 are from R plates taken with the CTIO 4 m telescope by W. A. Hiltner and C. Canizares. The chart for 2S1728-337 is from the southern extension of the Palomar Sky Survey (National Geographic Society). North is up and east is to the left. The flare star designated M (2S1636-536) has been suggested<sup>17</sup> as an optical counterpart. The 2S1636-536 and 2S1735-444 regions each contain a star (numbers 3 and 5 respectively) with a pronounced ultraviolet excess<sup>11</sup>.

## Identification of the $\lambda 2,200\text{\AA}$ interstellar absorption feature

A BROAD absorption feature centred on  $\lambda 2,200\text{\AA}$  with a half-width of  $\sim 300\text{\AA}$  appears in the spectra of reddened stars<sup>1–3</sup>. This conspicuous feature in the interstellar extinction curve, might hold an important clue to the identity of a major component of interstellar matter, but it has defied identification for over a decade. Here we identify this band as representing the integrated effect of a set of bicyclic compounds, each with the empirical formula  $\text{C}_8\text{H}_6\text{N}_2$ . Such nitrogenated structures could form in stellar mass flows of the type which we have also discussed<sup>4</sup>. A significant mass fraction of all interstellar material might exist in this form.

Graphite particles have been considered the most plausible candidate for the  $\lambda 2,200\text{\AA}$  absorption feature. Whilst a small particle resonance in graphite can occur close to  $\lambda 2,200\text{\AA}$ , the central wavelength of this feature is sensitively dependent on particle shape<sup>5</sup>. Spherical particles with sizes small compared to the wavelength are necessary to produce agreement with observational data, but a more realistic distribution of shapes would produce a considerably broader absorption feature than is required. It therefore seems that a narrower molecular absorption must be superimposed on an underlying broader extinction hump which could be caused by extinction from graphite grains with a wide spread in their shapes.

We have discussed a possible molecular origin for the  $\lambda 2,200\text{\AA}$  band due to  $\pi \rightarrow \pi^*$  electronic transitions in a wide class of molecules involving conjugated double bonds<sup>6</sup>. We now limit our search to the nitrogenated heterocyclic compounds listed in Table 1. The first four compounds represent all possible arrangements of two N atoms in a bicyclic structure, with the hetero-atoms confined to one ring only. The fifth compound is an isomer where there is one N atom in each of the two rings.

An average molar absorptivity function  $\langle \epsilon(\lambda) \rangle$  was computed for these materials from available spectroscopic data<sup>7</sup>. A normalised absorptivity  $A(\lambda)$  given by

$$A(\lambda) = \frac{\langle \epsilon(\lambda) \rangle - \langle \epsilon(\lambda_0) \rangle}{\langle \epsilon(\lambda_1) \rangle - \langle \epsilon(\lambda_0) \rangle} \quad (1)$$

with  $\lambda_0^{-1} = 3.8 \mu\text{m}^{-1}$ ,  $\lambda_1^{-1} = 4.55 \mu\text{m}^{-1}$  is plotted in Fig. 1. Our computed curve for  $\text{C}_8\text{H}_6\text{N}_2$  isomers agrees exactly with the interstellar extinction data with respect to the central wavelength, but the 'average' interstellar band is apparently  $\sim 30\%$  wider. The latter departure could easily be ascribed to an

Fig. 1 Normalised average molar absorptivity for  $C_8H_6N_2$  isomers (solid curve) compared with interstellar extinction data in the waveband  $3.8 \mu m^{-1} < \lambda^{-1} < 5.4 \mu m^{-1}$ . Normalisation is to 0.0 at  $\lambda^{-1} = 3.8 \mu m^{-1}$ , 1.0 at  $\lambda^{-1} = 4.55 \mu m^{-1}$ . Vertical bars give indication of spread of astronomical data. Dotted curve is the mean extinction curve of Bless and Savage<sup>2</sup> normalised according to equation (1). Open circles give mean extinction ( $E(\lambda - V)/E(B - V)$ ) relative to extinction data for  $\theta$ -Orionis, and normalised as above.

underlying graphite particulate extinction (scattering+absorption) peak upon which the narrower molecular absorption band is superposed. Since  $\theta$ -Orionis shows a broad extinction hump centred on  $\lambda 2,200\text{\AA}$  rather than the sharper band which is more common, we can reasonably attribute this extinction curve to an underlying graphite component. The mean extinction curve relative to the extinction data for  $\theta$ -Orionis (Fig. 1) provides much closer agreement with the molecular absorption data, as we would expect. The mass density of molecules necessary to produce the observed strength of the  $\lambda 2,200\text{\AA}$  interstellar band ( $\sim 1.5 \text{ mag kpc}^{-1}$ ) is  $\sim 10^{-27} \text{ g cm}^{-3}$  implying that only  $\sim 10\%$  of interstellar C and N is in this form.

An identification of ring compounds of the type listed in Table 1 may have important consequences. Linear molecules such as HCN,  $HC_3N$ ,  $HC_5N$ ,  $HC_7N$  which have already been observed in interstellar space may result from the break-up of

Table 1 Properties of various isomers of  $C_8H_6N_2$

Compound	Structural formula	$\lambda_m(\text{\AA})$	$\epsilon$ (molar absorptivity)
Cinnoline		2,250	40,000
Quinazoline		2,220	35,500
Quinoxaline		2,340	23,400
Phthalazine		2,150	56,000
1,5 Naphthyridine		2,060	54,000

these more complex structures. It would now be worthwhile to search systematically for ring molecules by radioastronomical techniques.

Sakata *et al.*<sup>8</sup> have reported the detection of an absorption feature at  $\lambda 2,200\text{\AA}$  in soluble organic material extracted from the Murchison meteorite. In view of the possible connection of this material with interstellar matter, a chemical analysis of the

molecules responsible for the meteoritic  $2,200\text{\AA}$  band will also be valuable. It is interesting that several nitrogen heterocyclic compounds, including purines, pyrimidines and pyrroles have recently been identified in carbonaceous chondrites<sup>9-11</sup>.

## Has the Sun a companion star?

PULSARS are accurate timekeepers. They are believed to be rotating neutron stars, with strong magnetic fields, and the energy they radiate is at the expense of their rotational kinetic energy<sup>1</sup>. As each pulsar ages, its period  $P$  (relative to the Solar System barycentre) slowly increases, and its period derivative  $\dot{P} (= dP/dt)$  slowly decreases. Certain interesting pulsars (displayed in Table 1) have anomalously small period derivatives, and rather surprisingly, are found grouped together in the same region of the sky (shown in Fig. 1). I suggest here, as an explanation of the peculiar properties of these pulsars, that the barycentre of the Solar System is accelerated, possibly because the Sun is a member of a binary system and has a hitherto undetected companion star.

The characteristic spindown age of any pulsar is  $T = P/\dot{P}$ . Most pulsars are born close to the galactic plane and most pulsars have high velocities; hence, as they age, they disperse away from the galactic plane. By studying the observed height distribution of pulsars about the galactic plane, various authors<sup>1-5</sup> have drawn the following conclusions.

First, the 'young' pulsars of  $T \leq 3 \times 10^6 \text{ yr}$  (or  $\dot{P} \geq 10^{-14}$ ) have an observed height distribution that shows a rise in scale-height with increasing  $T$ , that is consistent with the known velocities, and the spindown age is a reasonable approximation of true age.

Second, most pulsars (57 out of 85) of known period derivatives<sup>5,6</sup> are 'middle-aged' and have spindown ages in the range  $3 \times 10^6 \leq T \leq 3 \times 10^8 \text{ yr}$  (or  $10^{-14} \geq \dot{P} \geq 10^{-16}$ ). In their case  $T$  is generally an unreliable indicator of true age, and at best is an upper limit. This is possibly because of magnetic-field decay<sup>1,2,8</sup>, or change in magnetic-field orientation<sup>8-10</sup>, or perhaps because of other unknown processes. The positions of these 57 pulsars in equatorial coordinates are shown in Fig. 1; they are distributed about the galactic equator and show concentration toward the galactic centre.

Third, the remaining five pulsars of  $T \geq 3 \times 10^8 \text{ yr}$ , listed in Table 1, have anomalously low period derivatives of  $\dot{P} < 10^{-16}$ . PSR1913+16 is the binary pulsar discovered by Hulse and Taylor<sup>11</sup>, and its low period derivative  $\dot{P} = 9 \times 10^{-18}$  may be due to exchange of angular momentum. There are, at present, no explanations for the anomalously low period derivatives of the remaining four pulsars.

The period derivatives shown in Table 1 must be further reduced by the Shklovsky<sup>16</sup> or 'train-whistle' effect (whistle-blowing trains passing in all directions through a nearby railway station have positive  $\dot{P}$ ). If  $\dot{P}_0$  is the intrinsic period derivative of a source

moving with transverse velocity  $v_t$  at distance  $d$ , and  $\dot{P}$  is the observed period derivative, then

$$\frac{\dot{P}}{P} = \frac{\dot{P}_0}{P} + \frac{v_t^2}{cd} \quad (1)$$

where  $c$  is the velocity of light. For PSR1944+17 the Shklovsky effect reduces  $\dot{P}_0$  to almost zero<sup>17</sup>; and for PSR1952+29 it is found that  $\dot{P}_0$  is negative<sup>15</sup> and the pulsar is apparently spinning up. Mansfield and Rankin<sup>15</sup> have investigated various mechanisms that might explain the negative intrinsic period derivative of PSR1952+29, and conclude that all hitherto proposed mechanisms are either inadequate or unlikely.

Fig. 1 Plot of pulsar positions in equatorial coordinates on an equal area projection. ○, Pulsars of  $10^{-14} > \dot{P} \geq 10^{-16}$ ; ●, pulsars of  $\dot{P} < 10^{-16}$ ; C, Galactic centre.

The pulsars of small period derivative in Table 1 are shown with their positions plotted in Fig. 1. It is remarkable that all five lie in the same region of the sky with their right ascension ( $\alpha$ ) and declination ( $\delta$ ) within the ranges  $17^{\text{h}}30' < \alpha < 19^{\text{h}}52^{\text{m}}$  and  $-27^\circ < \delta < +32^\circ$ . Inside the box (shown in Fig. 1), defined by these coordinate limits, are found 23 pulsars of which five have the anomalously small  $\dot{P}$ ; outside the box are the remaining 39 pulsars, all of which have  $\dot{P} \geq 10^{-16}$ . The probability of a chance clustering of five pulsars in 23 out of 62 is about 1%. Even if chance explains the clustering effect, it does not explain the anomalously low  $\dot{P}$  values.

The above results suggest that the barycentre of the Solar System is accelerated in a direction that is within or close to the coordinate values already given. If  $\dot{V}$  is the acceleration of the Solar System in a direction defined by coordinates  $\alpha_0$ ,  $\delta_0$ , and  $\Delta\dot{P}$  is the change in  $\dot{P}$  of a pulsar located at coordinates  $\alpha$ ,  $\delta$ , then

$$\frac{\Delta\dot{P}}{P} = -\frac{\dot{V}}{c} \{ \sin\delta\sin\delta_0 + \cos\delta\cos\delta_0\cos(\alpha - \alpha_0) \} \quad (2)$$

Evidently,  $-\Delta\dot{P} \sim 10^{-16}$  is sufficient to account for the low values of  $\dot{P}$  in Table 1, including correction for the Shklovsky effect, and because  $P \sim 1$  s, this corresponds to an acceleration  $\dot{V} \sim 10^{-6} \text{ cm s}^{-2}$ . This acceleration is very roughly in the direction of the galactic centre but is at least two orders of magnitude greater than the acceleration of the Sun in the gravitational field of the Galaxy. (More precise values of  $\dot{V}$ ,  $\alpha_0$ ,  $\delta_0$  cannot be found by averaging a weighted  $\dot{P}$  over the celestial sphere. This is because of a selection effect: the pulsars in the direction of the galactic centre include those of higher displacement from the galactic plane and therefore they have lower average  $\dot{P}$ .)

An intriguing explanation of the acceleration  $\dot{V}$  is that the Sun has an orbiting companion star. The acceleration is then

$$\dot{V} = GM_c/R_c^2 = 0.6 M/R^2 \text{ cm s}^{-2} \quad (3)$$

and is directed toward the companion star of mass  $M_c$  at distance  $R_c$ , where  $M (= M_c/M_\odot)$  is its mass measured in units of the Sun's

Table 1 Pulsars of  $\dot{P} < 10^{-16}$

Pulsar	$P$ (s)	$\dot{P}$ ( $10^{-16}$ )	Age ( $10^8$ yr)	Distance (pc)	Refs

\*Binary pulsar

mass and  $R$  its distance in AU. A companion star of mass  $M \sim 1$  at distance  $R \sim 10^3$  therefore produces an acceleration that is approximately equal to  $\dot{V} \sim 10^{-6} \text{ cm s}^{-2}$ . The circular orbital period of the hypothetical star is

$$P_c = R^{3/2}(1+M)^{-1/2} \text{ yr} \sim 10^4 \text{ yr} \quad (4)$$

and the corresponding proper motion is  $\sim 100$  arc s per yr (the annual parallax is  $\sim 200$  arc s).

Most nearby stars are members of systems that contain two or more stars<sup>18</sup>, and several stars have unseen companions detected astrometrically. The possibility of the Sun possessing a faint companion star has so far not been entirely eliminated<sup>19</sup>. A hypothetical companion star of, say, an apparent magnitude  $m_v = 10$  (much too faint to be seen by the naked eye), has a luminosity  $\sim 10^{-9}$  times that of the Sun. It is conceivable that the companion star is a crystallised white dwarf<sup>20,21</sup> that has cooled rather rapidly to a surface temperature of less than  $10^3$  K during the lifetime of the Solar System. A red (or even black) dwarf<sup>22</sup> of mass  $M \lesssim 0.1$ , that has failed to ignite hydrogen (but may be burning deuterium), has an exceedingly low luminosity and is therefore also a plausible candidate. If, however, the companion is a neutron star or black hole, produced by a supernova in the early history of the Solar System, then it is difficult to understand how our weakly bound binary system has survived such a violent event. It is more likely that a companion neutron star or black hole is in hyperbolic orbit, and the present close encounter is a transitory phenomenon lasting only several thousands of years. The companion star is therefore presumably either a faint white or red dwarf in closed orbit about the Sun, or a gas-accreting nearby neutron star or black hole in open orbit. It should not be difficult to detect low-luminosity objects of this kind having large annual parallax and proper motion.

Obviously, a star in closed orbit about the Sun must lie close to the ecliptic plane so as not to disturb the planets excessively out of their common orbital plane. According to current theories on star formation<sup>23</sup>, stars and their planets condense in interstellar gas clouds, and therefore planets probably revolve in the same orbital plane as the parent stars of a binary system. A companion star orbiting close to the ecliptic is not inconsistent with the distribution of pulsars of  $\dot{P} < 10^{-16}$  shown in Fig. 1.

A companion star in closed orbit would produce various long-term effects within the Solar System. For example, the apsidal period  $U$  (the period of precession of perihelion) of a planetary orbit of period  $P_p$  is<sup>24,25</sup>

$$U = \frac{4}{3}(1+M^{-1})P_c^2P_p^{-1} \quad (5)$$

and hence, with  $M \sim 1$ ,  $P_p \sim 1$  yr,  $P_c \sim 10^4$  yr, this equation yields  $U \sim 10^8$  yr, and the precession amounts 0.5 arc s per century (or 0.1 arc s per century in the case of Mercury). Short-term perturbations in the motions of Neptune and Pluto are significant, but as far as I can determine, are not unacceptably large.

Long-term changes in climate are conceivably attributable to periodicities in the Earth's orbit<sup>26,27</sup>, that could be enhanced by the presence of a companion star, particularly if its orbit has appreciable ellipticity. Furthermore, cometary motions will undoubtedly be affected. According to Oort's comet-cloud theory<sup>28</sup>, the comets extend out to a distance  $\sim 10^5$  AU, and the comet cloud

therefore envelops the proposed binary system of the Sun and its companion star. Oort has suggested that the nearby stars, at a few light years distance, perturb the comet cloud and as a result comets continually diffuse into orbits of comparatively small perihelia. The proposed binary system would obviously play an even more effective role in stirring the cometary orbits, and could also explain why the comet cloud, during the lifetime of the Solar System, has expanded to its present size.

Has the Sun a companion star? I find it hard to believe that a star so close can exist and yet remain undiscovered. On the other hand, pulsar observations of extraordinary precision imply that it might exist, and therefore a search for a companion star is perhaps worth undertaking.

I thank T. T. Arny, D. J. Helfand, W. C. Saslaw, and particularly J. H. Taylor, for helpful comments, and also to the Aspen Center for Astrophysics for hospitality. Helfand has recently measured  $\dot{P}$  for PSR2106+44 and finds that for this pulsar:  $\dot{P} = -1.36 (\pm 1.00) \times 10^{-17}$ . It is interesting that this pulsar is in the same region of the sky as the other pulsars of anomalously low  $\dot{P}$ . I also thank Dr P. van de Kamp for his comments, and for pointing out that the 'train whistle effect' has been known since 1901 as 'perspective secular change in the line of sight'<sup>29</sup>.

## Lines of H<sub>2</sub> in extreme-ultraviolet solar spectra

THE first detection of H<sub>2</sub> in the Sun, in extreme ultraviolet spectra, is reported here. The Naval Research Laboratory's High Resolution Telescope and Spectrograph (HRTS), flown in a rocket on 21 July 1975, was used for these observations. The slit extended from Sun centre to limb and crossed a sunspot at 07° S, 23° W in McMath region 13766. This stigmatic spectrograph, described by Bartoe and Brueckner<sup>1</sup>, covered 1,175–1,714 Å with 0.06 Å spectral and 1.5 arc s spatial resolution. A full list of observed lines is in preparation<sup>2</sup>. The sunspot spectrum contains some 120 emission lines which do not correspond to known lines listed in compilations<sup>3</sup> of transitions in atoms or ions, apart from random coincidences. More recent publications referred to in the NBS Bibliography<sup>4</sup> were also consulted. The identifications of the lines which are enhanced in the sunspot spectrum will be discussed elsewhere<sup>5</sup>.

A short stretch of a spectrum obtained with a 51-s exposure time is reproduced in Fig. 1. The top spectrum is of the solar limb,

**Fig. 1** A short section of the stigmatic ultraviolet solar spectrum showing several of the Lyman band lines in the 1,440–1,510 Å region. Each of the two sections covers three different areas on the solar surface. The solar limb spectrum is at the top, the spot spectrum in the centre and the 'pore' spectrum at the bottom.

the centre one is of the sunspot and the lower one is of a region of the quiet Sun which contains a small area ( $\sim 2$  arc s) in which some of the sunspot lines are greatly enhanced (a 'pore').

At least three distinct types of lines are present. Some are observed in the spot, pore and at the limb (for example, the line at 1,446.13 Å in Fig. 1); others are restricted to the spot and limb or to the pore and limb.

The continuum in both the sunspot umbra and penumbra is below the instrumental threshold for detection even in the longest exposure of 51 s. At 1,600 Å this corresponds to an upper limit of 3,950 K for the region of formation of the continuum, compared with the normal quiet Sun value of  $\sim 4,400$  K. From their visible region spectra sunspots are found to have photospheric temperatures of  $\sim 4,400$  K, and the temperature minimum above a spot is typically considered to be  $\sim 3,200$  K (ref. 6). The visible region spectra are therefore characterised by the presence of low excitation absorption lines and by hundreds of absorption lines of molecular origin which do not appear in the normal photospheric spectrum. In the ultraviolet the known emission lines of singly ionised species decrease in intensity over the spot and only neutral lines formed deeper in the chromosphere are enhanced. The origin of the new lines is therefore restricted to species with low ionisation potentials or dissociation energies.

Because of the high abundance of hydrogen and the expected low temperatures, the molecule H<sub>2</sub> (dissociation energy 4.55 eV), which has strong far ultraviolet bands, is an obvious candidate for any new lines in the sunspot. An early comparison with known laboratory spectra<sup>7</sup> of H<sub>2</sub>, however, indicated no general agreement in the character of the spectra. In a 100 Å section near 1,500 Å there are of the order of 100 vibrational lines in the Lyman bands, whereas the sunspot spectrum over the same wavelength range shows only a few lines. Moreover, even allowing for different excitation conditions between the Sun and laboratory, most of the lines expected to be strong are absent.

But it has now been found that at least 30 of the new lines are due to known transitions in the Lyman bands of H<sub>2</sub>, the key to the appearance of the spectrum lying in the excitation mechanism for the lines.

The Lyman bands arise between the ground state  $1^1\Sigma_g^+$  and the excited state  $1^1\Sigma_u^+$ . The lines of many vibrational bands have been tabulated by Herzberg and Howe<sup>8</sup>, and a useful *Atlas of Intense Lines* has been prepared by Schubert and Hudson (unpublished Aerospace Report, ATN-64(9233)-2).

The most striking aspect of the lines which correspond to H<sub>2</sub> is that 13 of them can be identified at P-branch ( $J=5$ ) and R-branch

( $J=3$ ) transitions in the  $v'=1$  to  $v''=n(2<n<9)$  Lyman bands; only one line in each branch is observed in each band, all originating from a common  $v'=1, J'=4$  upper level. Progressions with upper vibrational quantum number  $v'=constant$  were first studied by Wood and Hackett<sup>8,9</sup> and are usually due to fluorescence.

The source of the fluorescence is not hard to find, given the high intensity of the nearby H L $\alpha$  line. The energy difference between the  $v'=1, J'=4$  level in  $^1\Sigma_u^+$  and the  $v''=2, J''=5$  level in  $^1\Sigma_g^+$  is within  $26\text{ cm}^{-1}$  of the energy of H L $\alpha$ . The full-width at half maximum (FWHM) of H L $\alpha$  is  $\sim 1\text{ \AA}$ . So the H<sub>2</sub> molecules in the sunspot, or pore, can be excited by photons in the red wing of H L $\alpha$  as they travel down towards the photosphere.

The observed lines from  $v'=1$  are listed in Table 1, together with their intensities in the umbra, and their FWHM. The theoretical intensity ratio<sup>10</sup> of P5 to R3 lines is 10/8, and within the limits of experimental accuracy the observed line intensities agree with this. Along the progression the intensities follow closely the relative strengths of the bands as predicted by the transition probabilities of Allison and Dalgarno<sup>11</sup>. The observed line widths correspond to a 'thermal' temperature of  $7.7 \times 10^3\text{ K}$ , or with  $T_e \sim 4,400\text{ K}$ , a nonthermal velocity of  $\sim 5\text{ km s}^{-1}$ .

\*The wavelengths are from Herzberg and Howe<sup>7</sup>. Solar wavelengths agree with laboratory wavelengths within 0.02  $\text{\AA}$ .

The 1-0 and 1-1 bands are outside the wavelength range of the instrument, but an 'anti-Stokes' line is observed at 1,202.45  $\text{\AA}$ . Other fluorescence occurs, accounting for transitions in the 0-4, 0-5 and 0-6 bands. To produce these the  $v'=0, J'=1$  and 2 levels are excited from  $v''=2, J''=1$  by photons  $104\text{ cm}^{-1}$  and  $134\text{ cm}^{-1}$  out into the red wing of H L $\alpha$ . The  $J''=9$  level is also excited but not apparently by photons. But its energy is close to that of the  $v'=1, J'=4$  level discussed above and collisional processes may be indicated. This second group of lines is listed in Table 2. There are a further 20 or so weak lines of similar appearance which correspond by wavelength to H<sub>2</sub> transitions but which do not show such systematic behaviour.

The closest coincidence with H L $\alpha$ , the transition between  $v'=3, J'=1$  and  $v''=3, J''=0$ , does not produce observable lines. This is probably due to the combined effects of the self-reversal of H L $\alpha$ , a lower transition probability and a lower population of  $v''=3$ .

The remaining lines, which do not appear in the pore, may also have a molecular origin, but the singly ionised rare-earths are another possible source of low excitation lines.

The aspects of the data which relate to the understanding of the solar atmosphere will be discussed in the forthcoming paper<sup>5</sup>. But

\*The wavelengths are from Herzberg and Howe. Solar wavelengths agree with laboratory wavelengths within 0.02  $\text{\AA}$ .

the importance of this H L $\alpha$ , H<sub>2</sub> fluorescence process extends beyond the solar atmosphere, since it will occur wherever strong L $\alpha$  radiation can penetrate a layer of temperature  $\sim 2,000\text{--}5,000\text{ K}$ . For example, one can immediately predict that these H<sub>2</sub> lines should be present in stars cooler than the Sun, particularly those of type early K, since the visible region spot 'special type' is K0. Such observations could be made with the forthcoming International Ultraviolet Explorer (IUE) Satellite, which includes the appropriate wavelength range. Further, Osterbrock<sup>12</sup> and Black and Dalgarno<sup>13</sup> have stressed the importance of the ultraviolet radiation field in the formation of the interstellar lines of H<sub>2</sub>. The penetration of L $\alpha$  from hot stars into nearby cooler media may play a particularly important role, although the low population of the  $v''=2$  levels will make fluorescence less effective than in stellar atmospheres.

## Significance of peroxyntiric acid in atmospheric chemistry of nitrogen oxides

KNOWLEDGE of the life cycle and budget of nitrogen oxides in the atmosphere is important for several reasons. In the stratosphere, NO and NO<sub>2</sub> (NO<sub>x</sub>) play a dominant part in maintaining the structure and stability of the ozone distribution. In the troposphere, NO<sub>x</sub> is involved in the production and destruction of OH radicals which control the fluxes of many important species such as CH<sub>4</sub>, CO, H<sub>2</sub> and CH<sub>3</sub>Cl, to the stratosphere. In polluted urban areas, NO<sub>x</sub> chemistry provides the basic formation mechanism of photochemical air pollution. In all these areas of atmospheric chemistry, the interactions of NO<sub>x</sub> with HO<sub>x</sub> species (HO, HO<sub>2</sub> and so on) are of great significance, particularly the reactions of HO<sub>2</sub> with NO and of HO with NO<sub>2</sub>. A further HO<sub>x</sub>-NO<sub>x</sub> interaction is the proposed<sup>1</sup> formation of peroxyntiric acid in reactions (1) and (-1):

We present here a study of the extent to which reaction (1) and (-1) acts as a sink for HO<sub>x</sub> and NO<sub>x</sub> in the atmosphere.

Peroxyntiric acid was first reported to possess rather low stability at room temperature in the gas phase<sup>1</sup>, decomposing back to HO<sub>2</sub> and NO<sub>2</sub> with a lifetime of about 50 s. Subsequently other groups<sup>2,3</sup> have identified infrared absorptions of HO<sub>2</sub>NO<sub>2</sub>, reporting much longer lifetimes, about 500 s, with the decay being ascribed to heterogeneous removal at the vessel walls. These apparently diverging conclusions can be rationalised if HO<sub>2</sub>NO<sub>2</sub> is in thermal equilibrium with HO<sub>2</sub> and NO<sub>2</sub> as we have shown to be the case for its organic analogue PAN (peroxyacetyl nitrate) and the corresponding peroxy radical, CH<sub>3</sub>CO(O<sub>2</sub>) (ref. 4). When NO<sub>2</sub> is in large excess over NO, as in the infrared experiments, the main fate of the HO<sub>2</sub> radical is to recombine with NO<sub>2</sub> reforming HO<sub>2</sub>NO<sub>2</sub> again. Only when nitric oxide can effectively compete against NO<sub>2</sub> for HO<sub>2</sub>, will HO<sub>2</sub>NO<sub>2</sub> decay at its unperturbed unimolecular decay rate,  $k_{-1}$ .

We have studied the temperature dependence of this competition for HO<sub>2</sub> radicals in reactions (1) and (5) by producing HO<sub>2</sub>

radicals from the photolysis of nitrous acid (HONO) in the presence of carbon monoxide (CO):

The photolysis was conducted in a flow system<sup>5</sup> with reaction times of 1–13 s. NO<sub>x</sub> was present at p.p.m. concentrations in synthetic air diluent at 1 atm pressure; NO, NO<sub>2</sub> and HONO were measured by chemiluminescence techniques<sup>6</sup>.

The observed time dependence of the nitric oxide concentration, [NO], reflects the balance between production by photolysis of HONO and NO<sub>2</sub> and by oxidation through the chain reaction sequence, (3) + (4) + (5) (see Figs 1 and 2). Figure 1 shows that [NO] usually declines, indicating the dominance of chain oxidation over photolytic production. But increasing the NO<sub>2</sub> concentration leads to decreased nitric oxide decay rates. The magnitude of the observed effect requires HO<sub>2</sub>NO<sub>2</sub> formation to be the explanation

**Fig. 1** NO concentration-time curves showing the effect of increasing NO<sub>2</sub> on the inhibition of NO oxidation in mixtures containing approximately  $2 \times 10^{14}$  and  $5 \times 10^{16}$  molecule cm<sup>-3</sup> of HONO and CO in 1 atm of air at 35 °C. Initial NO<sub>2</sub> concentrations, [NO<sub>2</sub>]<sub>0</sub> in molecule cm<sup>-3</sup> are: ●,  $1.78 \times 10^{13}$ ; ○,  $3.24 \times 10^{13}$ ; ■,  $5.90 \times 10^{13}$ ; ○,  $1.15 \times 10^{14}$ . Lines show computed curves used in estimating  $k_1/k_5$  and  $k_{-1}$ .

**Fig. 2** NO concentration-time curves showing the effect of temperature on the inhibition of NO oxidation by the addition of approximately  $1 \times 10^{14}$  molecule cm<sup>-3</sup> NO<sub>2</sub> to mixtures containing HONO and CO in 1 atm of air. Experimental points: ●, 40 °C; ■, 45 °C; ○, 55 °C. Lines show computed curves using  $k_1/k_5 = 0.22$  and  $k_{-1}$  values illustrated in Fig. 3.

rather than increased NO<sub>2</sub> photolysis. Figure 2 shows that the inhibiting effect of HO<sub>2</sub>NO<sub>2</sub> formation is only transitory. The initial increase in [NO] due to strong inhibition of the chain oxidation gives way to a steady decline at a rate almost independent of temperature. The induction period, representing the time taken for [NO] to reach its maximum, increases with decreasing temperature. This behaviour is exactly that expected for the formation of an intermediate which is thermally unstable with respect to active free radical chain carriers. Thus peroxyntiric acid is apparently a kinetically significant species in the HO<sub>x</sub>+NO<sub>x</sub> system at low temperatures.

Quantitative kinetic information was obtained by integrating the differential equations describing the reaction scheme, using the Harwell computer program FACSIMILE<sup>7</sup> and literature rate constants<sup>8</sup>. The values of  $k_1$  and  $k_{-1}$  were obtained by minimising

the sum of the squares of the deviations between observed and simulated [NO] against time curves. The experiments below 295 K gave consistent values of  $0.22 \pm 0.03$  for the rate constant ratio  $k_1/k_5$  in air at 1 atm total pressure. In these conditions the  $\text{HO}_2\text{NO}_2$  lifetime was longer than the residence time in the flow reactor so that redissociation was unimportant and the [NO] against time profile was determined primarily by the relative rates of reactions (1) and (5). This ratio  $k_1/k_5$  was then used at the higher temperatures to obtain the values of  $k_{-1}$  which are plotted in Arrhenius form in Fig. 3. A value of  $1.2 \times 10^{-12} \text{ cm}^3 \text{ molecule}^{-1} \text{ s}^{-1}$  (ref. 9) was adopted for  $k_5$  but neither  $k_{-1}$  or  $k_1/k_5$  were sensitive to the chosen value of  $k_5$  in the range  $10^{-11}$  to  $10^{-12}$ . The values of  $k_{-1}$  are represented by  $k_{-1} = 10^{16.1 \pm 1.6} \exp(-11,700 \pm 1,100/T) \text{ s}^{-1}$  for  $T$  in K at 1 atm pressure. The pre-exponential factor and activation energy,  $(97 \pm 9) \text{ kJ mol}^{-1}$ , are quite reasonable for the unimolecular decomposition of a weakly bound molecule into two radical fragments.

Fig. 3 Temperature dependence of the decomposition rate constant for  $\text{HO}_2\text{NO}_2$ ,  $k_{-1}$ : plot of  $\ln k_{-1}$  against  $10^3/T$  ( $\text{deg K}^{-1}$ ).

Decomposition lifetimes of  $\text{HO}_2\text{NO}_2$  calculated from the above expression for  $k_{-1}$  give some indication of the stability of  $\text{HO}_2\text{NO}_2$  at various altitudes in the atmosphere. In the coolest parts of the atmosphere near the tropopause, mean temperatures are about 220 K, corresponding to an  $\text{HO}_2\text{NO}_2$  lifetime of about 16 weeks (0.3 yr) with respect to thermal decomposition. As a result, the concentration distribution of  $\text{HO}_2\text{NO}_2$  in the upper troposphere and lower stratosphere will depend on the atmospheric circulation and dynamics as well as on the chemistry, provided that  $\text{HO}_2\text{NO}_2$  is not removed rapidly by photolysis and reactions with other stratospheric species. Calculations with a two-dimensional model indicate that as much as 30% of the total  $\text{NO}_x$  in the upper troposphere may become tied up as  $\text{HO}_2\text{NO}_2$ . This species may therefore play a similar role to  $\text{HNO}_3$  in providing a removal mechanism for stratospheric  $\text{NO}_x$ .

In the atmosphere near the Earth's surface  $\text{HO}_2\text{NO}_2$  is unstable with a decomposition lifetime of 9 s at 298 K.  $\text{HO}_2\text{NO}_2$  will therefore not provide a significant sink or store for  $\text{HO}_2$  or  $\text{NO}_2$ , merely existing at a low steady-state concentration in the sunlit atmosphere. Consequently  $\text{HO}_2\text{NO}_2$  is likely to have only a limited significance in photochemical air pollution and model calculations of photooxidant formation will not be seriously in error by omitting this species. This conclusion is in contrast to that of Levine *et al.*<sup>3</sup> who suggest that  $\text{HO}_2\text{NO}_2$  may be an important product of photochemical smog.

## Vertical profile of stratospheric ozone by lidar sounding from the ground

LIDAR measurements of stratospheric ozone by differential absorption (DIAL) technique were taken during July 1977 at the Haute-Provence Observatory (44N). A frequency doubled rhodamine 6G dye laser provided an output energy of 20-40 mJ in the wavelength range 300-310 nm. We report here preliminary measurements of stratospheric ozone in the altitude range 18-25 km. This experiment was carried out with the lidar facility previously used for the study of upper atmospheric metallic constituents at the mesopause level<sup>1</sup>.

The transmitting part of the lidar system consists of a flash-lamp pumped, frequency-doubled dye laser emitting in the wavelength range 300-310 nm. The experimental set-up is shown on Fig. 1 and its characteristics are summarised in Table 1. The dynamic range of this electronic system together with the close proximity of the emitting and receiving optical parts does not allow observations in a low altitude range (5-15 km); in order to avoid signal induced noise<sup>3</sup> or spurious signal from photomultiplier overloading, a rotating wheel protects the photomultiplier during the first 100  $\mu\text{s}$ . These constraints limit our experiments to an upper altitude range of 18-28 km. Observations have been conducted on two different nights (19-20 July, 20-21 July 1977) and more than  $5 \times 10^3$  laser shots have been registered and analysed.

The signal backscattered by Rayleigh diffusion in the altitude range  $z, z + \Delta z$  at a wavelength  $\lambda_1$  can be written as

$$N_R(\lambda_1, z) = N_L(\lambda_1) \frac{A}{z^2} \frac{d\sigma_r}{d\Omega}(\lambda_1) n_a(z) \Delta z \eta T^2(\lambda_1, z) \exp[-2\tau_{0.3}(\lambda_1, 0, z)] \quad (1)$$

where  $N_L(\lambda_1)$  is the number of emitted photons,  $A$  the telescope area,  $\eta$  the optical efficiency of the lidar system,  $d\sigma_r/d\Omega(\lambda_1)$  the

Table 1 Characteristics of the lidar system

Transmitter		Receiver	
Energy per pulse	20-40 mJ	Telescope area	0.5 m <sup>2</sup>
Output wavelength	303.7-308 nm	Beamwidth	$5 \times 10^{-3}$ rad
Linewidth	0.15 nm	Linewidth	3 nm
Beam divergence	$< 8 \times 10^{-4}$ rad		
Pulse duration	4 $\mu\text{s}$		
Pulse repetition rate	0.25 Hz		

The receiver is a 0.8-m Coudé telescope. Two interference filters were used for these observations: they are centred respectively at 308.2 nm and 303.7 nm with a peak transmission of 30% and a width of 3 nm (FWHM). These wavelengths have been selected to obtain a ratio of 1.75 in the absorption cross-sections of ozone and are compatible with an observation in the stratospheric range. The Rayleigh backscattered signal is detected by a trialkali cathode photomultiplier (EMR 541 E) and its temporal analysis is made by a multichannel analyser working in a photon counting mode with a vertical resolution of 1.2 km.

**Fig. 1** The laser experimental set-up. 1, High reflectivity mirror; 2, wavelength selecting prisms; 3, laser head; 4, dye cell; 5, linear flash tubes; 6, output mirror ( $R = 40\%$ ); 7, cylindrical lens; 8, crystal housing (UG5 output window); 9, ADP crystal. The oscillator head is made of three 15-cm length bielliptical cylindrical reflectors, successively mounted with a  $60^\circ$  angle between their plane of symmetry to obtain a total pumping length of 45 cm. Six linear flash tubes (VQX6FD15) are then used in this optical arrangement. The fundamental line (600–620 nm) is generated using an active solution of rhodamine 6G ( $10^{-4}$  Ml $^{-1}$ ) in water with 4% Ammonix LO. With water as a solvent, the length of the laser cavity has been increased up to 2 m to reduce the beam divergence to less than  $8 \times 10^{-4}$  radian, leading to a better efficiency in the Second Harmonic Generation (SHG)<sup>2</sup>. Spectral narrowing of the emitted line to 0.15 nm is made using two quartz prisms working at their minimum deviation angle, which are also used to polarise the emitted beam. Rotation of the high reflectivity mirror leads to the tuning of the output wavelength which can be controlled using a grating spectrograph (dispersion 0.3 nm mm $^{-1}$ ). The output energy of 1 J which is usually obtained with an efficiency of 0.25% in a shot by shot experiment, has been reduced to half of this value for the atmospheric observations in order to increase the lifetime of the electrical components and to reduce the photolysis of the lasing solution. An ammonium dihydrogen phosphate crystal oriented for critical phase matching angle at the selected output wavelength is used to perform the SHG with an energy efficiency of 5% to 10% depending on the output power of the fundamental beam. Due to the presence of a 3 mm-thick UG5 window at the output edge of the crystal housing, only the ultraviolet light is emitted in order to avoid contamination effect of the backscattered signal by the fundamental visible beam.

Rayleigh backscattering cross-section,  $n_a(z)$  the total atmospheric density and  $T(\lambda_1, z)$  the atmospheric transmission between the ground and altitude  $z$  in the absence of ozone absorption.

$$\tau_{03}(\lambda_1, 0, z) = \int_0^z \sigma_{03}(\lambda_1) n_{03}(h) dh$$

is then the optical thickness of ozone at wavelength  $\lambda_1$  on a one-way path between the ground and altitude  $z$ . Its value is derived

from the experimentally measured  $N_R(\lambda_1, z)$  assuming that ozone is the main absorber at wavelength  $\lambda_1$  between  $z$  and  $z + dz$ . Interference effects with other minor constituents ( $\text{SO}_2$ ,  $\text{H}_2\text{O}$ , aerosols) are important in the troposphere<sup>4</sup> but their concentration are thought to be too low in the stratosphere range to produce any detectable attenuation. Absorption by molecular oxygen is also negligible at 300 nm where the cross-sections are of the order of  $10^{-26}$  cm $^2$  (ref. 5) which leads to an optical thickness of  $10^{-3}$  for a 1.2 km resolution range.

The effect of aerosols around 22 km (ref. 6) should also be considered assuming a maximum extinction coefficient of  $4 \times 10^{-8}$  cm $^{-1}$  at 300 nm and thus an optical thickness of  $5 \times 10^{-3}$  which is again one order of magnitude lower than the expected ozone absorption. These assumptions will be confirmed later by comparing signals obtained at two different wavelengths. The only contribution to the atmospheric transmission  $T(\lambda_1, z)$  is then the total molecular extinction by Rayleigh scattering which can be written as  $T(\lambda_1, z) = \exp[-\tau_a(\lambda_1, 0, z)]$  where  $\tau_a$  is the optical thickness defined as:

$$\tau_a(\lambda_1, 0, z) = \int_0^z \frac{d\sigma_r(\lambda_1) n_a(h)}{d\Omega} dh$$

From the ratio:

$$R(\lambda_1, z, z + \Delta z) = \frac{N_R(\lambda_1, z)}{N_R(\lambda_1, z + \Delta z)} \frac{(z + \Delta z)^2}{z^2} \frac{n_a(z)}{n_a(z + \Delta z)} \times \exp[-2\tau_a(\lambda_1, z, z + \Delta z)] \exp[-2\tau_{03}(\lambda_1, z, z + \Delta z)] \quad (2)$$

and using an atmospheric density model for midlatitude summer conditions<sup>7</sup> to derive the values of  $[n_a(z)/n_a(z + \Delta z)] \exp[-2\tau_a(\lambda_1, z, z + \Delta z)]$ , we can now deduce the optical thickness of the ozone layer between  $z$  and  $z + \Delta z$ . Figure 2a and b show these values of  $\tau_{03}$  between 18 km and 28 km with a resolution of 1.2 km, as measured at two different wavelengths ( $\lambda_1 = 308.2$  nm,  $\lambda_2 = 303.7$  nm). The deviation from a pure Rayleigh atmosphere shows up clearly. The integration time, 3 h during the night of 20 July, corresponds to  $3 \times 10^3$  laser shots at

**Fig. 2** a, Deviation of the differential optical thickness at  $\lambda_1 = 308$  nm from a pure Rayleigh atmosphere ( $\tau_{03} = 0$  corresponds to the situation of pure Rayleigh scattering). b, Deviation of the differential optical thickness at  $\lambda_2 = 303.7$  nm from a pure Rayleigh atmosphere. ( $\tau_{03} = 0$  corresponds to the situation of pure Rayleigh scattering). c, Comparison of  $\tau_{03}(\lambda_1) - \tau_{03}(\lambda_2)$  as measured from equation (3),  $\tau_{03}(\lambda_1)$  and  $\tau_{03}(\lambda_2)$  normalised to the same absorption cross-section ( $10^{-19}$  cm $^2$ ). ( $\tau/\sigma = 0$  corresponds to the situation of pure Rayleigh scattering.) (●,  $\tau/\sigma$  (308.2 nm); ○,  $\tau/\sigma$  (303.7 nm); ■,  $(\tau(\lambda_1) - \tau(\lambda_2))/(\sigma(\lambda_1) - \sigma(\lambda_2))$ ).

both wavelengths and leads to the computed error bars, taking into account the statistical error of the received signals.

If we consider the ratio

$$\mathcal{R} = \frac{R(\lambda_1, z, z + \Delta z)}{R(\lambda_2, z, z + \Delta z)} = \exp -2[\tau_{O_3}(\lambda_1) - \tau_{O_3}(\lambda_2)] \quad (3)$$

we then obtain a direct determination of the ozone concentration without reference to any model. The backscattering by atmospheric particles has the same effect at two wavelengths and thus is eliminated. We have plotted on Fig. 2c the values of  $(\tau_{O_3}(\lambda_1) - \tau_{O_3}(\lambda_2)) \times 10^{19}/(\sigma_{O_3}(\lambda_1) - \sigma_{O_3}(\lambda_2))$ , together with the related error bars as computed from the received signal, assuming the following values for the absorption cross-section<sup>5,8</sup>

$$\sigma_{O_3}(\lambda_1 = 308.2 \text{ nm}) = 3 \times 10^{-19} \text{ cm}^2$$

$$\sigma_{O_3}(\lambda_2 = 303.7 \text{ nm}) = 5.2 \times 10^{-19} \text{ cm}^2$$

These values are directly related to the ozone concentration and are compared with the ratios

$$\frac{\tau_{O_3}(\lambda_1) \times 10^{19}}{\sigma_{O_3}(\lambda_1)} \text{ and } \frac{\tau_{O_3}(\lambda_2) \times 10^{19}}{\sigma_{O_3}(\lambda_2)}$$

which lead to the same physical quantity. This shows good agreement between the two methods of data analysis confirming the former assumptions and the neutral density modelling.

The vertical ozone profiles obtained on these two nights are presented in Fig. 3 together as an example with the statistical error bar as derived for one night (20–21 July). The accuracy of the measurement is directly calculated from the backscattered signals using equation (3) except for the upper part of the profile ( $z > 25 \text{ km}$ ) where the absorption at 303.7 nm is too strong to

Fig. 3 Vertical ozone profiles (○, 19–20 July 1977; ●, 20–21 July 1977).

allow a precise determination of  $\mathcal{R}$  using this channel.  $n_{O_3}$  is then obtained only from the 308 nm channel assuming a constant value for the atmospheric density scaleheight, as calibrated in the lower altitude range by comparison of  $\tau_{O_3}(\lambda_1)$  and  $\tau_{O_3}(\lambda_2)$ . The accuracy of these preliminary measurements precludes any conclusion about a possible day to day variation of the ozone content. Its vertical repartition shows a maximum around 22 km with a concentration of  $3 \times 10^{12} \text{ cm}^{-3}$  which is within the range of measurements by other methods<sup>9</sup> and model computations<sup>10</sup>.

Further improvements of this DIAL technique to measure the ozone vertical profile will be done soon by extending the altitude range of the observations. Measurements of the backscattered signal in the analogical mode will allow the determination of  $n_{O_3}$  between 10–20 km whereas, in the lower troposphere, interference effects by other atmospheric minor constituents must be carefully considered. In a same way an increase of the output wavelength of the ultraviolet laser up to 320 nm will reduce the ozone absorption in the lower stratosphere and thus extend the altitude range of observations up to 40 km. Furthermore, the accuracy of the experiment could be improved by increasing the output energy of the ultraviolet laser up to a factor of 3 as already obtained in laboratory and its repetition rate (up to 2 Hz). This differential absorption lidar technique will then provide a very powerful tool for the determination of stratospheric ozone concentration from ground based stations.

## Photomineralisation rate of organic compounds adsorbed on particulate matter

ATTEMPTS to correlate the concentration of chemicals in the environment with their production figures have resulted in a large deficit, especially for organic chemicals such as DDT<sup>1</sup>. It has been assumed that analytical errors accounted for this deficit. Another explanation, however, considers the reactions of compounds in abiotic conditions. As far as atmospheric chemistry is concerned, such an explanation needs a thorough knowledge of the kinetics and mechanisms of all possible reactions of a compound, including its products and also consideration of the meteorological conditions. Only then would it be possible to describe the time dependence of concentrations of organic compounds in the atmosphere with any accuracy. To consider all the data required is time-consuming and expensive, because of the rather complicated mechanisms of conversion and decomposition. We have therefore devised simple, standardised tests.

In previous experiments we demonstrated that even persistent chemicals were decomposed to  $\text{CO}_2$  (and in the case of chlorinated compounds also to  $\text{HCl}$  and/or  $\text{Cl}_2$ ) as solids in an oxygen stream<sup>2,3</sup>. The results of this decomposition—the photomineralisation—are given in Table 1. Cyclodiene insecticides, such as aldrin and dieldrin, mineralise during irradiation with Pyrex-filtered ultraviolet light. Using short-wave ultraviolet light ( $\lambda < 290 \text{ nm}$ ), the amount of mineralisation products is significantly increased. DDT, DDE and pentachlorophenol behave in the same way as aldrin and dieldrin, whereas results from irradiating pentachlorobenzene, hexachlorobenzene and certain chlorinated biphenyls (PCBs) lead us to assume that these compounds are only mineralised, when exposed to short-wave ultraviolet light. Photomineralisation is, therefore, a simple test evaluating the behaviour of chemicals in atmospheric conditions. The relative mineralisation rate which is used to compare one substance with others can be

**Table 1** Mineralisation products after ultraviolet irradiation of certain chlorinated hydrocarbons as solids in an oxygen stream

Compound	Mineralisation products (mg)			
	Quartz (2 d)		Pyrex (6 d)	
	CO <sub>2</sub>	HCl	CO <sub>2</sub>	HCl

About 80 mg of the respective compound was distributed on the inside wall of a 1-litre irradiation vessel and irradiated in an oxygen stream. The irradiation was carried out through quartz- and Pyrex-glass, using a Hg-high pressure lamp (HPK 125 W, Philips) as a light source.

\*Not determined.

†Not detected.

easily determined by the mineralisation products formed, such as CO<sub>2</sub>, HCl, Cl<sub>2</sub>. But standardised and well controlled test conditions are necessary.

As a considerable fraction of the organic compounds in the atmosphere is adsorbed on particles, we use carrier materials in photomineralisation experiments and because of their readily standardisable properties, silica gel and aluminium oxide are good carriers. Using a suitable ratio of test substance to carrier material, a constant, approximately monomolecular dispersion on the surface can be assumed. The resulting substance-oxygen contact is more effective than that of solids and with the catalytic effects of the carrier material will increase the mineralisation rate. In addition the application of carrier materials was found to be particularly useful for comparing gaseous, liquid and solid exponents.

The photomineralisation of some chlorinated alkenes (1, 1-dichloroethylene, tetrachloroethylene, 2,3-dichloropropene, 1,1-dichloropropene and hexachlorobutadiene),

**Fig. 1** Section of the irradiation apparatus for photomineralisation of adsorbed substances. The cylindrical reactor drum (1) is on one end linked by means of flanged joints, able to transmit power, with a drive motor (2) whose control is infinitely variable. On the other end a closed-ended irradiation tube (3) which is welded with a glass coupling and attached to the reactor drum by a coupling, projects into the interior of the reactor. The dimensions of the irradiation tube are chosen so that different sources of light (4) and filters can be used. On the inner wall of the reactor drum blades (5), parallel to the longitudinal axis, are inserted, which occupy only a fraction of the diameter and are adjusted into staggered positions starting from the front end. The weight of the reactor drum is carried by four rollers (6), which are connected to a support (7) by a holding device. On the support the flexible suspension for the drive motor is arranged. The reactor drum can be charged either through tube (10) at the stationary part of the apparatus or through tube (11) by applying a vacuum to tube (9). By rotation of the reactor drum along its longitudinal axis the reactants (carrier material with adsorbed phase and gas phase) are completely tumbled and mixed so that a homogeneous irradiation is guaranteed.

freons (trichlorofluoromethane and dichlorodifluoromethane) and aromatic hydrocarbons (benzene, toluene, and *ortho*-, *meta*- and *para*-xylenes) in the adsorbed state was carried out in a special irradiation apparatus (Fig. 1)<sup>4</sup>. About 1.3 g of the test substance was applied to 800 g of silica gel using a stream of nitrogen gas. The amount of substance actually adsorbed was determined by gas chromatography and by elementary analysis. Silica gel (350 g) containing the test substance were introduced into the irradiation drum which was then evacuated twice to 100 mm Hg and flooded with pure oxygen (at a drum capacity of about 25 l, a large excess of oxygen is ensured in respect to a total mineralisation of the initial amount adsorbed). The ultraviolet irradiation of the adsorbed substances was carried out with a Hg-high pressure lamp (HPK 125 W, Philips) using filters of quartz or Pyrex glass for 3 or 6 d respectively. After the irradiation the mineralisation products, such as CO<sub>2</sub>, Cl<sub>2</sub> were driven off from the reactor drum by a carrier gas (N<sub>2</sub>) and trapped by passing the gas through two wash bottles connected in series, each containing 50 ml of 0.1 M NaOH solution. CO<sub>2</sub> was quantitatively determined by acidometric titration of CO<sub>3</sub><sup>2-</sup> and Cl<sub>2</sub> by iodometric titration of OCl<sup>-</sup>. The quantitative determination of mineralisation products which could not be eluted from the silica gel (such as HCl) was done by mixing silica gel with a NaOH solution (0.1 M) and subsequent potentiometric titration of Cl<sup>-</sup> with AgNO<sub>3</sub>. Table 2 and Fig. 2 show the results of the photomineralisation of the chlorinated alkenes, freons and aromatic hydrocarbons. In

**Fig. 2** CO<sub>2</sub>-formation of aromatic hydrocarbons adsorbed on silica gel by ultraviolet-irradiation. Percentages are given by moles CO<sub>2</sub> formed divided by moles CO<sub>2</sub> expected from a total mineralisation of the initial amount adsorbed. *a*, Pyrex, 6 d; *b*, quartz, 4 d. 1, Benzene; 2, toluene; 3, *o*-xylene; 4, *m*-xylene; 5, *p*-xylene.

all cases CO<sub>2</sub> was found; in the case of chlorinated compounds HCl and/or Cl<sub>2</sub> were also found.

The photomineralisation of chlorinated alkenes is the most effective as shown in Table 2. The quantity of the formed mineralisation products is not noticeably influenced by using quartz- or Pyrex-filtered ultraviolet light. The increased amount of products in the Pyrex experiments are due to the extended irradiation times. This indicates a possible photomineralisation with ultraviolet light predominating in the troposphere ( $\lambda > 290$  nm). Even the freons which are well known as highly persistent compounds are degraded to CO<sub>2</sub> and HCl by using Pyrex-filtered light. But here the degradation with short-wave ultraviolet light is slightly favoured.

In contrast to the chlorinated alkenes and freons, the aromatic compounds in the solid state and adsorbed on silica gel show a higher persistence with respect to a photomineralisation. While irradiating through Pyrex glass only low mineralisation rates were found. Using quartz-filtered

§50–90%  $\text{CO}_2$ -formation.

light, however, a significant increase could be determined (Table 1 and Fig. 2).

An even greater distinction within one class of compounds is possible: by comparing benzene with toluene and the xylenes (Fig. 2) a tendency to higher  $\text{CO}_2$ -formation was found. Moreover, the three xylenes showed differences due to the steric position of their methyl groups. These results are supported by the determination of the remaining amounts of aromatic hydrocarbons after irradiation.

From these examples a characteristic behaviour of certain compounds as well as classes of substances becomes evident, which might help in evaluating organic chemicals with regard to their degradation in environmental conditions.

## Formation of Fe-Ni-Si planetary cores

THE planets may have accreted inhomogeneously materials accumulating on the proto-planets in the sequence in which they condense at high temperatures (1,000–2,000 K) out of the solar nebula<sup>1</sup>. The first solids to condense from the Earth, however, are the Ca and Al oxides, silicates and titanates<sup>2,3</sup> and not Fe or Fe-Ni alloy, which is supposed to form the Earth's core. Anderson and Hanks<sup>4</sup> consider that such a nucleus of oxides enriched in radioactive elements could provide a mechanism for heating and melting the surrounding solid Fe layer which accretes later. Ringwood<sup>5</sup> considers this model of core formation unsatisfactory since it may produce a layer of oxide rich material around the core for which we have no geophysical evidence. For Fe, or an alloy of Fe with other

elements, to form as the first equilibrium solid, the pressure in the solar nebula at 1,800 K must be several atmospheres<sup>3,6</sup>. But, the conditions for the formation of a liquid Fe or a liquid Fe-rich alloy have not been determined. If a liquid alloy formed as the first condensate, it would solve many problems in the current models of formation of planetary cores<sup>5</sup>. The pressure required to form a liquid alloy is likely to be an order of magnitude lower than the pressure for the formation of solid Fe because metal liquid solutions of Fe, Ni and Si have a lower free energy of solution than that of an ideal solution. In particular the Fe-liquid and Si-liquid, and Ni-liquid and Si-liquid form binary solutions with a low free energy which stabilises the liquid solutions at pressures lower than that of the solid. According to Podolak and Cameron<sup>6</sup> the models of Jupiter have an enhanced O-H ratio of ~25–30. They consider that pressure required to form chondrules will be lowered several orders of magnitude if the O/H ratio is increased. We report here an investigation into the equilibrium condensation of the solar nebular gas at 1,900 K at varying total pressures and varying abundance of hydrogen ( $A_H$ ).

The system consisted of 10 elements H, O, Al, Mg, Fe, Ni, C, Si, S, Ca in solar abundance<sup>7</sup> and over 70 gaseous and condensed compounds for which thermochemical data are available in sources listed by previous workers (such as Grossman<sup>8</sup>). The condensed compounds included forsterite and a number of liquid solutions of Fe, Ni and Si. These three elements were selected because they are liquids at 1,900 K. The vapour pressures of all other elements are low at 1,900 K and therefore none dissolves in the melt in any significant concentration. None of the oxides, titanates and other silicates condense at 1,900 K.

The free energies of the formation of liquid solutions were calculated using the expression

$$G = RT \sum X_i \ln X_i \gamma_i$$

Where  $G$  is the free energy of formation of the solution,  $X_i$  the mole fraction,  $\gamma_i$  the activity coefficient,  $R$  the gas constant and  $T$  the absolute temperature. For a ternary solution,  $\gamma_i$  is given by<sup>8</sup>:

$$\ln \gamma_i = X^2 [E_{ij} + 2 X_i (E_{ji} - E_{ij})] + X^2_k [E_{ik} + 2 X_i (E_{ki} - E_{ik})] + X_{jk} [0.5 (E_{ji} + E_{ij} + E_{ki} + E_{ik} - E_{jk}) + X_i (E_{ji} - E_{ij} + E_{ki} - E_{ik}) + (X_j - X_k) (E_{jk} - E_{kj}) - (1 - 2X_i) C]$$

Where the  $E$  values are the binary interaction coefficients and  $C$  is the ternary constant. Here we neglect the ternary constant. The data on binary coefficients are  $E_{\text{Fe-Si}} = -5.77$ ,  $E_{\text{Si-Fe}} = -7.41$ ,  $E_{\text{Ni-Si}} = -6.75$ ,  $E_{\text{Si-Ni}} = -19.43$ ,  $E_{\text{Fe-Ni}} = -0.67$  and  $E_{\text{Ni-Fe}} = -0.67$ . These coefficients have been calculated from the thermochemical data given by Fruehan<sup>9</sup> (Fe-Si), by Kubachewski *et al.*<sup>10</sup> (Ni-Si) and by Elliot *et al.*<sup>11</sup> (Fe-Ni).

The results of the calculations are shown in Fig. 1 and Table 1. Following the practice of Herndon and Suess<sup>12</sup>, in Fig. 1, we used the hydrogen depletion factor (here defined as  $D_H = \log A_H$  in solar gas/ $A_H$  chosen to vary the ratio; no other element is depleted). Under most conditions of pressure, and varying  $A_H$  the liquid that forms does not differ appreciably in composition from  $\text{Fe}_{0.9}\text{Ni}_{0.05}\text{Si}_{0.05}$ . At normal hydrogen abundance, the liquid does not form until the pressure exceeds 1 atm. With decreasing  $A_H$  ( $D_H = 1$ ) the minimum pressure at which liquid forms is between 0.1 and 0.2 atm. The amount of liquid increases rapidly with increasing pressure and by 1 atm most of the Fe and Ni have condensed along with forsterite ( $\text{Mg}_2\text{SiO}_4$ ). A significant amount of Fe and Ni (~60%) condense as liquid solution without any admixture with forsterite between 0.1 and 0.3 atm. Therefore if such conditions of pressure and hydrogen depletion could exist in the nebula over a length of time an alloy core with an outer layer of alloy and forsterite could form.

With a further decrease in  $A_H$  ( $D_H = 2$ ) the minimum pressure for liquid formation lies between 0.01 and 0.05 atm. This liquid, however, does not contain any Si. The concentration of

$A_H$ , hydrogen abundance. The compositions of the liquid solutions are approximate.

Si in liquid increases with pressure. At such a hydrogen abundance, Mg is nearly 100% condensed as forsterite at all pressure considered in this study.

Our conclusions are: (1) A core of liquid alloy could form from a gas of solar composition only at relatively high pressures of the order of 1 to 2 atm. (2) This pressure could be lowered by

Fig. 1 Percentage of elements condensed based on the results of phase equilibrium calculations. Fe, Ni and Si condense as liquid solution, Mg and Si as  $\text{Mg}_2\text{SiO}_4$ .  $D_H$  values as 0 (dotted line), 1 (solid line) and 2 (dashed line) represent hydrogen abundances of  $2.6 \times 10^{10}$ ,  $2.6 \times 10^9$  and  $2.6 \times 10^8$  respectively.

about a factor of 10 if hydrogen is depleted by a similar factor. (3) A greater hydrogen depletion ( $D_H = 1$ ) results in stabilising forsterite down to 0.01 atm (and lower). Significant amount of liquid ( $\text{Fe}_{0.94}\text{Ni}_{0.06}$ ) forms only at 0.5 atm which could be regarded as the lowest pressure for the formation of the liquid. (4) Silicon may be the light element component of the alloy only if pressures are higher than 0.2–0.3 atm. In the pressure range considered (0.2 to 1.5 atm) the concentration of silicon in the liquid solution varies between 3 and 5%. If the O/H conditions can be deduced from other mineral–chemical information, an appreciable concentration of Si in the metal phase could indicate formation at high nebular pressure.

We thank Drs A. E. Ringwood and R. Brett for helpful suggestions. Part of this work was done while S.K.S. was visiting Dr M. J. Drake at the Lunar and Planetary Laboratory, University of Arizona, Tucson. Phase equilibria was computed using a program from Dr G. Eriksson, University of Umeå, Sweden.

## Angle of subduction

PLATE tectonics is well established as an empirical description for modification of the Earth's outermost solid layer, although the dynamics of the plates are poorly understood. One view is that the plates are surface manifestations of the deep mantle convection which must inevitably occur if there are deep-seated energy sources<sup>1</sup>. Mantle convection, however, may not be an efficient driver of plate motions<sup>2</sup>, and the negative buoyancy of subducting slabs may be more important<sup>2, 3</sup>. We consider here a simple fluid dynamical model which illustrates some of the general principles of subduction dynamics, and suggest an explanation for the observed subduction angle (the angle between the subducting slab and the Earth's surface). The model depends on the concept of a 'critical' negative buoyancy that plate material must attain before it can undergo steady-state subduction.

Observations indicate that the subduction angle  $\theta_s$  is seldom near  $0^\circ$  or  $90^\circ$  but is typically an intermediate value, say  $50^\circ$  (refs 4, 5). This does not seem to be explainable by trench migration (or the relative motion of plates) alone<sup>5</sup>. Jischke<sup>6</sup> explained the angle by proposing that the subducting slab adheres to the overriding continent, so that its angle of descent is dictated by the continental geometry, but this is only satisfactory for near surface behaviour. A detailed force-balance or energy-balance model might correctly predict  $\theta_s$ , but only by a fortuitous choice of poorly known parameters such as the average mantle viscosity  $\mu$ . In the energy minimisation calculation by Tullis<sup>8</sup>, for example, there is only a narrow range of  $\mu$  for which the predicted  $\theta_s$  is not near  $0^\circ$  or  $90^\circ$ . We propose, instead, that  $\theta_s$  is essentially independent of the poorly known mantle viscosity and plate rheology, and is determined by the requirement that the torques on the slab are balanced for the lowest possible negative buoyancy. The highly simplified model that we consider predicts  $\theta_s \sim 63^\circ$  for a non-migrating trench. Slab rigidity is fundamental to our model, but since the forces acting on the slab are a function of depth, deformation and even fracture of the slab may eventually occur and play a role in mantle seismic mechanisms<sup>7</sup>. Torque balance, however, with an appropriately chosen slab length, is a suitable first approximation for estimating  $\theta_s$ .

For simplicity, we assume that the mantle has a uniform viscosity and is convectively neutral, so that the only motion within it is that caused by the plates. We consider a two-dimensional model in which the trench and upper (non-subducting) plate are at rest (see Fig. 1). The subducting slab is assumed to be rigid and moving at a steady speed  $U$ . For the purpose of calculating the induced mantle flow only, it is also assumed to be infinitely long and infinitesimally thin. This is

Fig. 1 Two-dimensional model for a subduction zone (see ref. 7). Material is transported from the ridge (to the right of the diagram) and undergoes subduction at 0. The upper plate is at rest.

the model considered by McKenzie<sup>8</sup>, whose results we use here. He gives the hydrodynamic contribution to the pressure in regions A and B of Fig. 1 are  $P_A(\theta)$ , and  $P_B(\theta)$  respectively, where

$$P_A(\theta) = \frac{2\mu U [\sin \theta - \sin(\theta - \theta_s)]}{r[(\pi - \theta_s) + \sin \theta_s]}$$

$$P_B(\theta) = \frac{-2\mu U [\sin \theta \sin \theta_s + \theta_s \sin(\theta_s - \theta)]}{r[\theta_s^2 - \sin^2 \theta_s]} \quad (1)$$

$\theta$  is the polar coordinate measured anticlockwise from the upper plate, and  $r$  is the radial coordinate measured from 0. The lubrication resulting from shear heating<sup>8</sup> and the diapiric upwellings which are responsible for behind-arc spreading<sup>9</sup> both modify these pressure estimates at small  $r$ , but this does not greatly affect the torque balance that we consider.

Since  $P_A(\theta_s) > 0 > P_B(\theta_s)$  for all  $\theta_s$ , the hydrodynamic pressure difference across the slab always acts to reduce  $\theta_s$ . The torque about 0 due to this suction is  $T_H$  per unit trench length, where

$$T_H = \int_0^L [P_A(\theta_s) - P_B(\theta_s)] r dr$$

$$= 2\mu UL \left[ \frac{\sin \theta_s}{(\pi - \theta_s) + \sin \theta_s} + \frac{\sin^2 \theta_s}{\theta_s^2 - \sin^2 \theta_s} \right] \quad (2)$$

and  $L$  is the length of the subducting slab (assumed independent of  $\theta_s$ ). We assume that  $T_H$  is balanced by the gravitational torque  $T_G$  caused by the negative buoyancy of the slab. If  $\Delta\rho(r)$  is the density contrast between slab and mantle, and  $h$  is the slab thickness, then

$$T_G = \int_0^L \Delta\rho(r) g h r \cos \theta_s dr$$

$$= \frac{1}{2} b L^2 \cos \theta_s$$

$$b = g h \int_0^1 \Delta\rho(x) dx \quad (3)$$

where  $x = r^2/L^2$ ,  $g$  is the gravitational acceleration, and  $b$  is the mean negative buoyancy per unit slab area. The inclusion of  $h$  in our definition of  $b$  emphasises that subduction is aided either by increasing the density contrast or by thickening the plate. We neglect the torque required to maintain the bend in the subducting plate. Although this cannot be justified *a priori*, it should be noted that whereas the work done at the trench may be large, it does not follow that the corresponding torque on the subducting slab is necessarily large.

The graphical solution of  $T_H = T_G$  is shown in Fig. 2. Since  $T_H > 0$  for  $0 \leq \theta_s \leq \pi$  it follows that, for a fixed  $U$ , there is no solution for  $b$  sufficiently small. A solution becomes possible at a critical negative buoyancy  $b_c$  and a critical subduction angle  $\theta_c$  when the curves for  $T_H$  and  $T_G$  touch. The critical solution is

$$\theta_c \approx 63^\circ, b_c \approx 20\mu U/L \quad (4)$$

For  $b > b_c$ , two solutions are possible. The larger solution for  $\theta_s$  is stable since any small perturbation from it clearly leads to a restoring torque. The smaller solution for  $\theta_s$  is unstable, since any small deviation from it is amplified. The simple model predicts that  $\theta_s < 63^\circ$  is never stable. Subduction at these angles may be possible because of the finite torque required to bend the slab or the hydrodynamic pressure on the leading edge of the slab<sup>2</sup>.

This calculation provides no information on the onset of subduction since it concerns a steady state for which a well-developed subduction slab already exists. A model by Davies<sup>10</sup> may partly explain the initial subduction angle. We also do not consider the force balance along the direction of subduction which determines  $U$ . This balance is affected not only by the negative buoyancy and hydrodynamic effects<sup>2</sup>, but also by viscous drag on the subducting plate and ridge pushing (gravitational sliding)<sup>11</sup>. It is likely that  $U$  is not strongly dependent on  $\theta_s$ , but must itself exceed a critical value that is determined by the requirement that shear heating produce adequate lubrication below the plate between ridge and trench<sup>12, 13</sup>.

The following speculative but plausible picture emerges: after subduction is initiated, the trench migrates until a steady-state is reached where newly subducting material has the critical negative buoyancy  $b_c$  and subducts at an angle  $\theta_c$ .

**Fig. 2** The torques (in units of  $2\mu UL$ ) as a function of subduction angle. The three cosine curves labelled by values of  $b$  are for  $T_G$ . The remaining curve is for  $T_H$ . There is no solution for  $T_H = T_G$  if  $b < b_c$ , and a solution becomes possible at  $b = b_c$  when the curves just touch.

The negative buoyancy results from the thickening and cooling of the plate as the material proceeds from ridge to trench. The observed scatter of actual values for  $\theta_s$  results from the inevitable interaction between several ridge and trench systems, and the inability to achieve steady-state. The following plausible values satisfy equation (4) for  $b_c$ :  $\Delta\rho \sim 0.1 \text{ g cm}^{-3}$ ,  $h \sim 100 \text{ km}$ ,  $U \sim 10 \text{ cm yr}^{-1}$ ,  $L \sim 1,000 \text{ km}$ ,  $\mu \sim 2 \times 10^{22} \text{ P}$ . The size of the plate depends on the time taken for plate material to achieve critical negative buoyancy and, therefore, depends on the geothermal heat flux. This dependence may help to explain why plate tectonics was apparently so different in the Precambrian<sup>14</sup>.

The model we present here is oversimplified and incomplete, but it illustrates how the general physical principles of subduction might be identified. The choice of model is best made by comparing different tectonic systems, and data on the plate tectonics for the Earth at a different epoch or for other planets is essential for future progress.

After this work had been completed, the very closely related calculations by Tovish *et al.*<sup>15</sup> were brought to our attention.

We thank A. L. Hales and A. E. Ringwood for useful comments.

## Age and tectonic implications of the Baie d'Audierne basic-ultrabasic complex

MAJOR deformational and metamorphic events in the south-armoric metamorphic belt of south Brittany have been considered to be either Cadomian and Variscan<sup>1</sup> or Ordo-Silurian (Ligerian) and Variscan<sup>2</sup> in age. Geological interest in southern Brittany is, at least in part, focused upon the blueschists<sup>3</sup> and the basic-ultrabasic complexes of the area. The largest of these basic-ultrabasic complexes is that of the Baie d'Audierne group (Fig. 1). Although lacking suitable material for direct radiometric or stratigraphical dating, several indirect attempts have been made to date this group, using field data. These are briefly outlined here. It is proposed that the deformational and metamorphic history of this complex is entirely Variscan in age. The implications of this conclusion for the recently proposed plate-tectonic model of Cogné<sup>2</sup> are discussed.

The south-armoric metamorphic belt comprises a suite of non-fossiliferous, pre-Stephanian sediments, commonly ascribed to the late Proterozoic Brioverian<sup>4</sup>, which have been folded, metamorphosed and intruded by basic and ultrabasic rocks, granites and granite gneisses<sup>5,6</sup>. In the Baie d'Audierne region (Fig. 1), two divisions within the metamorphic rocks, an upper and a lower suite separated by an unconformity have been recognised<sup>7–9</sup>. It is thought that the lower suite was folded and metamorphosed in the amphibolite facies (kyanite grade) during the late Proterozoic Cadomian orogeny<sup>8</sup> before the deposition of the upper suite. The upper suite commenced with the deposition of a basal sedimentary series, the Languidou gneiss. Ordovician to Carboniferous sediments lie offshore of the Baie d'Audierne; their relationships to the upper suite is, however, uncertain<sup>9</sup>. In the Baie d'Audierne, the upper suite is cut by the Pors Poulhan granite gneiss (Fig. 1) which has yielded a whole rock Rb/Sr isochron at  $334 \pm 8 \text{ Myr}$  ( $\lambda^{87}\text{Rb} = 1.47 \cdot 10^{-11} \text{ yr}^{-1}$ ). This radiometric date has been interpreted as the magmatic cooling age of the granite. Subsequently, the whole sequence, upper and lower suites and the intruded Pors Poulhan granite, was folded by upright folds on east-west axes and metamorphosed in the albite-amphibolite facies during the Variscan orogeny<sup>8</sup>. Late Variscan granites intrude all the metamorphic rocks and are probably associated with other south-armoric granites emplaced into rocks of Upper and Lower Palaeozoic age<sup>11</sup>.

During recently completed fieldwork in the area where Cogné and Peucat defined the upper and lower Brioverian, in the Baie d'Audierne region (Fig. 1), I was unable to recognise any unconformity. The upper and lower suites throughout the area show a common structural and metamorphic history. In addition, the Languidou gneiss, interpreted by Cogné<sup>7</sup> as a metaconglomerate and used by Peucat<sup>8</sup> to support the postulated unconformity, is thought to be an intrusive granite containing partially assimilated xenoliths of country rock. The supposed 'pebbles' are deformed feldspar porphyroblasts and quartz-feldspar segregations. The Languidou gneiss shows the same pre-tectonic relationship to the surrounding metasediments as the Pors Poulhan gneiss. This pre-tectonic relationship also applies to an association of gabbro and peridotite (now amphibolite, garnet-pyroxenite and serpentinite, ascribed by Peucat to his lower suite) which intrude the metasediments. Following the intrusion of these ultrabasic to granitic rocks, the entire complex (the Baie d'Audierne group<sup>6</sup>) was isoclinally folded and metamorphosed in the amphibolite facies, up to sillimanite grade, with the development of an axial planar schistosity. This early schistosity was deformed by rare isoclinal folds and

**Fig. 1** Present-day distribution of the Baie d'Audierne group (a), south Brittany migmatites, (b) the Ile de Groix blueschists (c) and the spatial relationship to the Brioverian and Palaeozoic sediments north of the South Armorican Shear Zone (d); the blueschists may originally have been more widely separated from the mainland migmatites as they are bounded north and south by faults, possibly thrusts<sup>24</sup>. L, Languidou; P, Pors-Poulhan. 1, Cap Sizun gneisses; 2, Port Manech gneiss; 3, Morbihan; 4, Basse Loire (After Cogné<sup>1</sup>).

these in turn are refolded by upright folds on east-west axes, with a variably developed associated crenulation cleavage. The complex then underwent a mimetic annealing recrystallisation which did not produce any major retrogression of the earlier mineral assemblages. A subsequent retrogression in the greenschist facies is associated with the emplacement of the latest Variscan granites. A fuller account of the Baie d'Audierne area is given elsewhere<sup>6</sup>.

Similarly, the structural discordance representing the lateral extension of the unconformity within the metasediments of the metamorphic belt south of the South American Shear Zone has been observed neither in Morbihan<sup>12</sup> nor Basse Loire<sup>13</sup> (Fig. 1). From the above model, all the structural and metamorphic events affecting the rocks of the Baie d'Audierne group occurred between the emplacement of the Pors Poulhan gneiss and that of the late Variscan granites. If we accept the  $334 \pm 8$  Myr age given by the Pors Poulhan gneiss as an emplacement age, then the folding and metamorphism in the Baie d'Audierne area must have occurred entirely within the Upper Palaeozoic and forms part of the Variscan orogeny.

To the east, south east of the Baie d'Audierne, a suite of migmatites and anatectic granites outcrops (Fig. 1), within which the anatectic granite represents the culmination of migmatization<sup>1</sup>. To the south of the migmatites, metamorphic rocks of the blueschist (glaucofanite-lawsonite) facies outcrop on the Ile de Groix<sup>3,14,15</sup>. The anatectic granites have yielded a whole rock Rb/Sr isochron at  $363 \pm 12$  ( $\lambda^{87}\text{Rb} = 1.47 \times 10^{-11} \text{ yr}^{-1}$ ) (ref. 16). A premigmatization orthogneiss (Roguedas) has yielded a Rb/Sr whole rock isochron age at 460 Myr ( $\lambda^{87}\text{Rb} = 1.42 \cdot 10^{-11} \text{ yr}^{-1}$ ) (ref. 17), so fixing the migmatization between 460 Myr and 363 Myr. The diapiric rise of the anatectic granites is syn-second phase deformation in the surrounding migmatites<sup>18</sup>. This, in conjunction with the radiometric data, suggests the presence of a polyphase history of pre-Variscan<sup>2</sup>, high temperature metamorphism and deformation to the east whose early events and climax are older than the proposed post-334 Myr orogenic activity in the Baie d'Audierne to the west.

The radiometric ages for the migmatite suite are broadly similar to those for the time range of blueschist metamorphism

on the Ile de Groix (420–370 Myr) (ref. 17) as inferred from Rb/Sr mineral and whole rock data ( $\lambda^{87}\text{Rb} = 1.42 \cdot 10^{-11} \text{ yr}^{-1}$ ). A K/Ar 335 Myr mineral age has been suggested for this blueschist metamorphism<sup>19</sup>, which may, however, represent a later thermal event. In view of the spatial association of the above mentioned radiometric ages, rock types and metamorphic facies, it is possible to place the rocks of the Baie d'Audierne within the context of recently proposed tectonic models for south Brittany<sup>2,20</sup>. Such a tectonic context is necessarily confined to the south of the South Armorican Shear Zone due to the uncertainty concerning the movement history on this major tectonic line (P. Jegouzo, personal communication) and, therefore, the questionable validity of direct correlation between the south american metamorphic belt and central or north Brittany, the British Isles and so on.

The dominant strike trend in the Baie d'Audierne region is  $070^\circ$  (ref. 6); that of the migmatite belt to the east-south east is  $110-120^\circ$  (ref. 1). A gently curved arc can be envisaged, truncated by the late Variscan granites and mylonites of the South Armorican Shear Zone. Before the emplacement of these granites and the subsequent shear zone movement, the Baie d'Audierne group, which extends westwards to the edge of the submarine continental shelf<sup>9</sup>, would have extended to the east-north east, around the northern flank of the migmatite belt (Fig. 2). Whether or not the migmatite belt extended south of the present outcrop of the Baie d'Audierne group cannot be ascertained, as this position is occupied by a large, late Variscan granite (Pont l'Abbé). It is with this pre-late Variscan granite configuration in mind that the tectonic significance of the Baie d'Audierne group is discussed.

At, or even before, ~420 Myr ago, blueschist metamorphism was taking place to the south of a high temperature-medium

**Fig. 2** Proposed configuration of rocks of Baie d'Audierne (a), Migmatite Belt (b) and Ile de Groix blueschist (c) types pre-emplacement of the late Variscan granites. The true location and lateral extent of (c) cannot be ascertained<sup>24</sup>. Dashed lines indicate suggested boundaries.

pressure belt within which anatexis eventually occurred<sup>2</sup>. Relict areas of older granitic material (Port Manech and Cap Sizun gneisses) within the western part of the high temperature zone<sup>1,6,17</sup> suggest that the migmatite belt lay on, or immediately to the south of, continental crust (Fig. 3). The metamorphic belt therefore comprised an Andean type margin with a northward dipping subduction zone<sup>2,20</sup>.

Metamorphism and deformation of this margin during the Ordo-Silurian (Ligerian) orogeny<sup>3</sup> was related to subduction and the eventual arrival of northward moving continental material (Fig. 3), now lying immediately south of the blueschists (micaschists, granites and undifferentiated Palaeozoic sediments of the South Brittany continental shelf<sup>2,21</sup>). In the Baie d'Audierne area, sometime between the initiation of subduction (~420 Myr) and 334 Myr ago, rifting occurred

**Fig. 3** Non-scaled diagram of postulated plate boundary relationships during the Palaeozoic, representing an hypothetical approximately north-south cross section across Fig. 2: 1, Baie d'Audierne type basic and ultrabasic rocks; 2, south Brittany migmatites; 3, Ile de Groix blueschists associated with oceanic crust; 4, northern continental block; 5, southern continental block. Post-420 Myr/pre-334 Myr plate motions (solid arrows) involve northward subduction at the southern margin of the migmatitic island arc (2), behind-arc extension (1) and northward movement of the southern continental block. Post-334 Myr, the behind-arc rift closes (open arrows), as the island arc + southern continent (2+5) collide with the northern continental block (4). (Adapted after Cogné<sup>2</sup>).

within the continental plate just to the north of the migmatite belt (Fig. 3). Into this rift, mantle derived gabbro and peridotite were intruded, representing the initial stages in the development of a marginal basin behind an island arc<sup>22</sup>, now deeply eroded and represented by the migmatite belt. (A mid-ocean ridge origin for these basic and ultrabasic rocks has also been suggested<sup>8,23</sup>.)

At or post ~334 Myr ago, the migmatitic island arc, then in contact with the southern continental block (Fig. 3), was pushed northwards against the northern continental block, folding the behind arc rift zone and producing the Variscan deformation and metamorphism seen in the Baie d'Audierne. This continent plus island arc-continent collision corresponds to Cogné's intercontinental collision of the same age<sup>2</sup>. In Cogné's model, however, the 'suture' representing this collision is marked by the South Armorican Shear Zone to the north (Fig. 1).

The south-armoric metamorphic belt was situated therefore, at an active Andean type continental margin about 420 Myr ago, which after passing through a phase of back-arc rifting, progressed to a collision with a southern continent plus island arc and the northern continent, post 334 Myr ago.

## Spike responses of 'non-spiking' visual interneurone

OUR understanding of information processing in nerve nets has been modified by the concept of graded signal transmission<sup>1</sup>. Descriptions of non-spiking interneurons in insects<sup>2-8</sup>, and the demonstration of graded synaptic transmission<sup>3</sup> have contributed to this development. In the fly visual nervous system, second and higher order interneurons are known, which apparently do not produce action potentials<sup>6-8</sup>. We show here that at least eight individually identifiable movement-sensitive cells, which have the characteristic properties of non-spiking interneurons<sup>2</sup> will generate spikes with imposed hyperpolarisation. Their graded mode of operation is due to maintained refractoriness. This applies selectively to neurones, which belong to either of two anatomically, and physiologically distinct classes. Other cell types in the same preparation generate spikes spontaneously.

The third visual neuropil of flies contains two conspicuous sets of directionally-selective movement-sensitive neurones<sup>9,10</sup>—an array of 10 'vertical cells' (VS 1-VS 10) which respond to vertical movements in the ipsilateral visual field, and an array of three 'horizontal cells' (HS 1-HS 3) which respond to horizontal rotary movements in the visual field of the two eyes<sup>7,8</sup>. Figure 2a-f shows some of the characteristic responses to visual stimuli of the neurone VS 1 depicted in Fig. 1. Its membrane potential in the dark is about -41 mV, modulated by sparse synaptic activity (Fig. 2a). Illumination of the receptive field causes a small depolarisation and a marked increase in 'noise' (Fig. 2b). When a striped pattern moves upwards in the receptive field, the cell is hyperpolarised, and the noise reduced (Fig. 2c). With downward movements it is depolarised, and the noise increased (Fig. 2d). Clockwise (Fig. 2e), or counter-clockwise (Fig. 2f) horizontal movements are ineffective. The movement responses are largest at a pattern speed of 2 periods per s, thus corresponding to the velocity-dependent optomotor behaviour of intact flies<sup>11-13</sup>. It is possible to record this kind of electrical activity from any one of the VS- or HS-cells for more than 1 h, without ever

**Fig. 1** Neurone VSI of the blowfly *Calliphora erythrocephala*, as reconstructed after procion yellow injection, and serial sectioning. The right half of the fly's brain is shown from behind. Neuropil areas are white, tracts and perikaryon layers are shaded. The retinotopic projection of the ipsilateral visual field into the plane of the third visual neuropil (lobula plate) is indicated. VSI belongs to a set of 10 large movement sensitive neurones, which occupy the caudal face of the neuropil. Their dendritic arborisations are in the lobula plate, the somata are in the caudal surface layer, and their axon terminals are close to the oesophageal canal (EC). Field axes: a-p, antero-posterior (horizontal); d-v, dorsoventral (vertical); arrow: site of penetration.

**Fig. 2** Responses of neurone VS1 to visual stimulation. *a*, In darkness the membrane potential is  $V = -41$  mV, and the average noise is 0.6 mV r.m.s. *b*, With constant illumination  $V$  shifts by +2.4 mV, but the noise increases threefold (1.8 mV r.m.s.). *c-h*, Responses to pattern movements. The pattern is illuminated throughout, and starts moving at the broken line. *c*, Upward movement hyperpolarises by  $-8.4$  mV, and reduces the noise; *d*, downward movement depolarises by 11.0 mV, and increases the noise; *e*, clockwise, or *f*, counterclockwise horizontal movements give no significant responses. No spike is present in *a-f*. With steady hyperpolarisation, by injection of  $-2.4$  nA, upward movement (*g*) still elicits a graded hyperpolarising response ( $-7.6$  mV), but the effect of downward movement (*h*) is drastically different from (*d*): as well as an increased average depolarisation (+17 mV) fast spikes of about 30 mV amplitude are generated. These cannot be elicited by steady injection of depolarising current. Stimulus field:  $45^\circ$  lateral,  $60^\circ$  diameter; pattern: grating of 10° period; speed:  $20^\circ \text{ s}^{-1}$ ; brightness:  $50 \text{ cd m}^{-2}$ , contrast: 80%.

observing a full-sized action potential. No spikes are elicited by various other kinds of visual stimuli (such as intense flashes, discrete moving objects) or by depolarising currents up to 10 nA.

VS- and HS-cells, like the neurone VS1 shown here, apparently have the specific properties of 'non-spiking' interneurons<sup>2</sup>, namely: (1) small average membrane potential ( $-30$  mV to  $-50$  mV), (2) conspicuous noise-like potential fluctuations, (3) graded response to stimulation, (4) inability to generate action potentials with imposed depolarisation, and (5) graded transmission across chemical synapses of either polarity. This last property could not be tested here by simultaneously recording from postsynaptic neurones, but estimated length constants in VS and HS axons would allow graded potential changes to spread from the dendritic arborisation to the axon terminals. Any VS or HS cell will, however, generate spikes, if it is steadily hyperpolarised by current injection. The current required varies from less than  $-1$  nA to about  $-5$  nA and is inversely correlated with the membrane potential before current injection. The records in Fig. 2*g, h* are from the same neurone, VS1, as those in Fig. 2*a-f*, with the only difference that  $-2.4$  nA are continuously injected through the recording microelectrode by means of a balanced bridge circuit. The cell responds to pattern movements as before, but Fig. 2*h* shows in addition fast spikes which often ride on top of small depolarising voltage fluctuations. These

spikes have a fast repolarising phase, their amplitude increases with current and may overshoot ground potential. The current-induced hyperpolarisation of the cell membrane does not exceed the equilibrium potential of the inhibitory synaptic ion channels: as Fig. 2*g* shows, there is still a hyperpolarising response. The current effect is reversible, and with steady injection, the generation of spikes may continue for more than 2 h. These findings were repeatedly confirmed for 6 of 10 VS cells, and for 2 of 3 HS cells. Figure 3, for instance, shows spikes from the neurone HS1 which are elicited by excitatory post-synaptic potentials (e.p.s.p.s), but only if the cell is hyperpolarised. The same effects are expected from the remaining 6 neurones in the two classes, and are independent of the electrode-filling solution (5% Procion yellow M4RAN, 5% Procion rubine MX-B, isotonic potassium chloride).

The relationships between injected current, membrane potential, spike rate and spike amplitude, as studied more extensively in a VS neurone, are shown in Fig. 4. With increasing hyperpolarising current the spike rate rises rapidly from  $-1.5$  nA to  $-3.0$  nA, and declines again to zero between  $-3.0$  nA and  $-5.5$  nA, although the stimulation was stationary (constant light). The average membrane potential changes from  $-30$  mV at 0 nA to  $-60$  mV at  $-5.0$  nA. The spike amplitude increases non-linearly with current, and overshoots ground potential if more than  $-3.0$  nA are injected. The significant features of these spikes, namely their large amplitude, positive peak potential, and fast rate of repolarisation are not likely to arise from either chemical or electrical synaptic potentials, charging an otherwise electrically passive membrane.

**Fig. 3** Overshooting action potentials from neurone HS1, during steady hyperpolarisation with  $-1.0$  nA. The spikes are elicited by large e.p.s.p.s, evoked by horizontal pattern movement in the contralateral visual field. In one of the three superimposed traces no spike is generated and the e.p.s.p. is clearly visible. Records were taken at  $5^\circ \text{C}$  in order to spread the membrane processes in time, thereby circumventing the lowpass characteristic of the microelectrode ( $240 \text{ M}\Omega$ ; 5% procion yellow M4RAN).

Rather, they demonstrate the existence of voltage-controlled conductance channels with kinetic properties appropriately tuned to produce regenerative action potentials. Accordingly Fig. 4 indicates that the current range of more than  $-5$  nA corresponds to the resting state in a conventional neurone,  $-2$  nA to  $-5$  nA to an excited state, whereas between 0 and  $-2$  nA the membrane is refractory. In a schematised notion of electrical excitability this means that most sodium channels are inactivated, and a large proportion of potassium channels are open. This state would be unstable unless the resulting outward potassium current is balanced by an inward current of equal strength. Either leakage or a constant and strong excitatory synaptic input could provide the inward current. Switching off the stimulating light reduces the synaptic 'noise' (Fig. 2*a*) without significant increase in membrane potential. The more

Fig. 4 Spike rate (○) and spike amplitude (●) as functions of injected current in a VS neurone of *Calliphora*. Weak stationary excitation is provided by constant illumination (Fig. 2b). With increasing hyperpolarisation of the cell membrane, the spike rate ( $\pm$  s.e.m.) rises and falls steeply. At  $-5.0$  nA the membrane potential is  $-60$  mV, and the spike amplitude of  $80$  mV overshoots ground potential. The dependence of spike rate on membrane polarisation, the overshoot, and the fast repolarising phase (Fig. 3) characterise regenerative action potentials.

probable cause of the depolarised state is, therefore, a steady inward leakage current.

An interesting consequence with respect to the 'noisy' appearance of the membrane potential in the non-spiking state arises from the rapid breakdown of spike rate and spike amplitude between  $-2.5$  and  $-1.5$  nA in Fig. 4. In this poorly-defined state of the regenerative mechanism small fluctuations of synaptic or leakage currents will be amplified into comparatively large potential fluctuations. Noise measurements in this experiment yielded  $0.78$  mV r.m.s. at  $0$  nA,  $0.75$  mV r.m.s. at  $-5.5$  nA, but  $2.8$  mV r.m.s. at  $-2.0$  nA, where recognisable spikes contribute less than  $0.3$  mV r.m.s. to the overall noise.

These results show that VS and HS neurones have electrically excitable membranes. Their graded mode of operation is due to refractoriness of the regenerative membrane mechanism. Consequently neither natural nor imposed depolarisation will elicit spikes. The conspicuous membrane potential 'noise', which characterises the non-spiking state, is mainly caused by abortive membrane excitation. It is not clear why these cells in particular should be refractory, whereas other cells generate spikes. The advantage of permanent refractoriness is questionable; moreover, it has been shown in *Limulus* that electrical excitability can be differentially damaged in closely adjacent cells<sup>14</sup>. The 'non-spiking' state may therefore not represent the natural condition of information processing in these neurones.

## Evolutionary adjustment of developmental time in mixed populations of flour beetles

IN dense, synchronised laboratory populations of the flour beetle *Tribolium castaneum* (referred to here as CS), there is a substantial amount of cannibalism of the earliest pupating individuals by large larvae, thus creating the possibility of strong selection pressure against fast development<sup>1–3</sup>. An opportunity to investigate this possibility was provided by the existence of a set of mixed-species cultures that had been maintained for several years. These cultures contain CS and *T. confusum* (CF) in varying proportions. Since developmental time of CF is from 1–2 d longer than CS<sup>4</sup>, the null hypothesis of no differences in developmental time of CS from the various cultures could be tested against the alternative that developmental time of CS would increase as the proportion of slower developing CF in the culture increases. I report here that developmental times do in fact adjust in mixed populations of these flour beetles.

As part of a study of changes in competitive ability and other fitness components in populations of CS exposed to differing proportions of intra- and interspecific 'competition', two replicate series of nine cultures were established in 1968 using beetles from new, genetically heterogeneous stocks of CS and CF. The cultures are maintained at  $29^{\circ}\text{C}$ , 50–70% relative humidity in half-pint milk bottles containing about 30 g of whole wheat flour enriched with 5% brewer's yeast. At the beginning of each transfer, or cycle of selection, the nine cultures receive 200 adults, distributed among the two species as follows: culture number (1), 200 CS/0 CF; (2), 175 CS/25 CF; (3), 150 CS/50 CF; (4), 125 CS/75 CF; (5), 100 CS/100 CF; (6), 75 CS/125 CF; (7), 50 CS/150 CF; (8), 25 CS/175 CF; (9), 0 CS/200 CF. The initial adults are discarded 3 weeks after being placed in the cultures, thus insuring a minimum of one generation in each transfer. About 7 weeks later, the cultures are censused and the initial composition is re-established.

In these conditions CF is clearly inferior to CS; Fig. 1 shows that the percentage of CF recovered is always lower than the percentage used to initiate the cultures. In fact, only cultures 8 and 9 (often 7 and occasionally 6) produce enough CF adults to re-establish the initial number. The CF beetles used to reinitiate the deficient cultures come from cultures 8 or 9.

Developmental time was measured in the summer of 1973 on the progeny of beetles taken from the 28th transfer using standard procedures<sup>4</sup>. For each culture in each of the two series, two replicate vials were set up containing 150 eggs 0–24 h of age in 6 g of flour–yeast medium. Numbers of pupae were recorded by sex at daily intervals starting 18 d after egg laying.

Fig. 1 % CF recovered from cultures 1–9 of the two series, compared to the % used to initiate the cultures (dotted line) for the first three transfers, or cycles of selection. Open and closed circles represent the two replicate series of cultures.

Since developmental time is not normally distributed<sup>4</sup>, analyses were done on vial means, which were based on from 98 to 137 individual observations.

Developmental time data are shown in Fig. 2. Cultures 8 are obviously very different from cultures 1–7. Ignoring cultures 8, a factorial analysis of variance was carried out using the vial means from cultures 1–7. Main effects were series (2), cultures (7) and sexes (2). The only significant main effect was cultures ( $F = 9.88$ ,  $P < 0.001$ ). The culture  $\times$  series interaction was significant at the 0.05 level; this effect is a real one as will be shown below. Although differences between males and females have been found in some studies<sup>4</sup>, they were not evident here. Sexes were pooled for subsequent analyses.

Regression of developmental time on culture number for cultures 1–7 was carried out separately for each series. Linear regression was a significant source of variation for both series, and in one case there were also significant deviations from regression. The test for equality of slopes of the two regression lines showed that the slopes were not different, so a common line is plotted in Fig. 2. There is clear evidence for an increase in developmental time as a function of culture number.

Fig. 2 Developmental time (from egg to pupa) for CS from cultures 1–8 and CF from culture 9. Data points are means of 98–137 individuals. Open and closed circles represent the two replicate series of cultures. The line from cultures 1–7 is a common regression line for the two series. The regression equation is  $y = 20.12 + 0.08x$ .

Turning now to cultures 8; developmental times changed dramatically to the point where they are even slower than the CF controls in cultures 9. It might be argued that this is a result of inbreeding rather than natural selection, since cultures 8 are reinitiated with only 25 adults at each transfer and developmental time is known to be subject to severe inbreeding depression in CS<sup>5</sup>. I argue here, however, that the change is an adaptive one.

First, inbreeding depression also leads to a great increase in variability of developmental time<sup>5</sup>, as does artificial selection for slow development<sup>4</sup>. Coefficients of variation for developmental time in controls (cultures 1) and cultures 8 were 5.84 and 7.78 for series A, and 8.68 and 8.33 for series B; clearly in series B at least the coefficient of variation is not larger in culture 8. This argues against inbreeding depression.

Second, fecundity is known to be also subject to severe inbreeding depression in this species<sup>6</sup>. Fecundity data, obtained in separate egg cannibalism experiments, will be published elsewhere. In one of the two series, the fecundity of females from culture 8 was not lower than that of the other populations, and in the other series there was a linear decrease in fecundity with culture number. These results do not support the hypothesis of inbreeding depression.

Finally, note that cultures 8 are the only ones where CF always replaces itself; 70–90% of the surviving adults at the time of census are CF. In addition, there is a marked similarity

between Figs 1 and 2. Pearson product-moment correlation coefficients were calculated for developmental time versus percentage CF for both the 1st and the 28th transfers (Table 1). The correlations for transfer 1 are both significant, in agreement with the hypothesis. Most remarkable, however, are the extremely high correlations at transfer 28. In the two series, 94 and 99% of the between-culture variation in developmental time can be accounted for by differences in the percentage CF among surviving adults.

Table 1 Coefficients of correlation ( $r$ ) and determination ( $r^2$ ) between mean developmental time in CS and competitive ability

Series		Transfer 1	Transfer 28
A	$r$	0.76*	0.97†
	$r^2$	0.57	0.94
B	$r$	0.89†	0.99†
	$r^2$	0.79	0.99

Competitive ability was measured as % CF among surviving adults.

\* $0.05 > P > 0.01$ .

† $P < 0.01$ .

The hypothesis that developmental time of CS should increase as the proportion of slower developing CF in the cultures increases is supported by my data. The proposed mechanism of selection for slow development is cannibalism of early pupating individuals by large larvae. This mechanism was first suggested by Sokal and Sonleitner<sup>1</sup> as an explanation for increased developmental time in experimental CS populations. Using an artificial mixture of genotypes, I have shown that in dense cultures of CS there was strong selection against early pupation<sup>3</sup>. With increasing culture number in the present experiments there is a linear increase in the proportion of CF adults used to initiate the culture, but a distinctly non-linear increase in the proportion of CF among the survivors (Fig. 1). Developmental times of CS from these cultures form a very similar non-linear curve (Fig. 2). The high correlations between developmental time and percentage CF in the cultures at the time they were first established might conceivably be spurious ones involving some other, unknown, selective agent. But the extremely high correlations at transfer 28 are clearly suggestive of an adaptive response.

I thank Russel Riddle and Catherine Samollow for assistance, and John Wiens for comments on the manuscript. The research was supported by the USNSF.

## Bismuth staining of Golgi complex is a characteristic arthropod feature lacking in *Peripatus*

THE traditional view for the origin of arthropods is that an exoskeleton has evolved once and the three major modern groups, Crustacea (for example, crabs), Chelicerata (spiders) and Uniramia (insects) had a common ancestor in the pre-cambrian. This ancestor was itself related to primitive Onychophora (present day representative, *Peripatus*) and ultimately to predecessors of the annelids<sup>1–4</sup>. But, arthropods may have had two, three or several separate evolutionary origins if the external features thought to unite the groups have evolved in response to functionally similar requirements<sup>3,5</sup>. Studies on

trilobite skeleton, for example, suggest two independent ancestral groups whose members were not themselves arthropods. These gave rise on the one hand to the Uniramia and on the other to the chelicerates which were linked to Crustacea through ancestral trilobites<sup>6</sup>. The discovery of a cell component characteristic of all cell types in insects<sup>7</sup> prompted a systematic study of its distribution, to see if it could be of help in determining arthropod evolutionary relationships. We report here that a characteristic feature of arthropods, bismuth staining of the Golgi complex beads, is absent in *Peripatus*, thus supporting the established view of arthropod evolution.

The smooth surface of the rough endoplasmic reticulum that makes the forming face of the Golgi complex in all cell types in *Calpodes* (Lepidoptera, Hesperidae), has particles arranged like beads on a circular string with about 10 beads per ring and a centre-to-centre spacing of 27 nm. Each particle has a core 11 nm in diameter that stains specifically with bismuth. The rough endoplasmic reticulum membrane distends through the bead rings to form the transition vesicles of the Golgi complex. Particles with the distribution described for *Calpodes* may be present in most Golgi complexes but unless they stain with bismuth they are difficult or impossible to resolve. In some vertebrate tissues, for example, particles with the appropriate distribution do not react with bismuth and can only just be resolved after uranyl staining<sup>8</sup>. These results suggested that the beads or functionally comparable structures may be a general feature of Golgi complexes in organisms and that the bismuth staining might have a meaningful but restricted phylogenetic distribution. We therefore surveyed a number of arthropods and their near allies to determine the distribution of the bismuth staining of beads.

Tissues from organisms in the phyla listed in Table 1 were fixed in glutaraldehyde, stained only in bismuth solution before embedding<sup>9</sup> and sections viewed with a Philips 300 electron microscope at a magnification of 250,000 and kept within 400 nm of focus. A piece of *Calpodes* tissue was carried through with each test specimen to make sure that failure to stain was not caused by an undetected failure of the technique. The success of the bismuth staining could also be judged by the reaction with interchromatin and perichromatin granules present in most nuclei. In practice there was rarely any doubt whether stained beads were present on suitably prepared Golgi complexes. They were usually found within minutes of beginning an observation or not at all, even after hours or days of searching. It may be that modification of the staining procedure could stain beads unrecognised hitherto, but the variations in staining recorded here reflect a consistent difference not attributable to variations in procedure.

**Table 1** Groups in which bismuth-stained Golgi complex beads are present (+) and absent (—)

Cnidaria		( <i>Condylactis</i> , <i>Hydra</i> )	—
Platyhelminthes		( <i>Bipalium</i> , <i>Pseudoceros</i> , <i>Planaria</i> )	—
Nematoda		( <i>Phoconema</i> )	—
Mollusca		( <i>Placopecten</i> , <i>Anodonta</i> )	—
Annelida		( <i>Spirorbis</i> , <i>Sabella</i> , <i>Tubifex</i> )	—
Onychophora		( <i>Epiperipatus</i> )	—
Tardigrada		( <i>Hypsibius</i> )	+
Arthropoda	Pycnogonida	Pantopoda (Undetermined)	+
	Chelicerata	Xiphosura ( <i>Limulus</i> )	+
		Acarina (Parasitidae)	+
		Pseudoscorpionidea (Undetermined)	+
	Crustacea	Isopoda (Undetermined)	+
		Decapoda ( <i>Orconectes</i> )	+
	Diplopoda	Polydesmoidea (Undetermined)	+
	Insecta	Orthoptera ( <i>Locusta</i> )	+
		Hymenoptera ( <i>Apis</i> )	+
		Coleoptera ( <i>Tenebrio</i> )	+
		Lepidoptera ( <i>Calpodes</i> )	+

Figure 1 shows some of the results. The characteristic size and spacing described for bismuth-stained GC beads in *Calpodes* is a constant feature throughout the arthropods. Table 1 shows the phylogenetic distribution. The beads are present in all three major arthropod groups and also in pycnogonids and tardigrades. They are absent from Onychophora (*Epiperipatus*),

**Fig. 1** Bismuth staining of the Golgi complex beads in the main arthropod lines of evolution. *a*, Uniramia, Insecta, *Calpodes*, Lepidoptera, Hesperidae, larval epidermis. *b*, Crustacea, Decapoda, *Orconectes* x-organ. *c*, Chelicerata, Arachnida, Acarina, epidermis. *d*, Pycnogonida, Pantopoda, epidermis. *e*, Chelicerata, Merostomata, Xiphosura, *Limulus*, epidermis. The tissues were stained only by bismuth which reacts with particles about 10 nm in diameter arranged in rings upon the smooth face of the rough endoplasmic reticulum where transition vesicles of the Golgi complex arise. The square bracket marks the characteristic 27 nm spacing. Stained beads are absent from all tissues in *Epiperipatus*. Scale bar, 100 nm.

annelids, molluscs and flatworms. The inclusion of the tardigrades with arthropods agrees with work showing chemical similarities between the cuticles<sup>10</sup>. The distribution of beads thus favours a common origin for present-day arthropods and makes it unlikely that the Uniramia arose separately from a *Peripatus*-like ancestor.

## Induction of fibrin thrombi by monocytes

THE discovery that blood clots in the absence of its cellular components has suggested that coagulation is independent of blood cells<sup>1</sup>. This view has been modified by the demonstration of procoagulant factors in the platelets<sup>2</sup> and anticoagulant heparin in basophils<sup>3</sup>. Procoagulant activity has also been found in extracts of leukocytes<sup>4,5</sup>, showing that coagulation is a cell-regulated phenomenon. We report here the direct observation of focal clotting induced by specifically activated monocytes.

Orientated fibrin micro-clots can be produced by incubation of bacterial endotoxin, the white cell buffy coat and heparinised plasma from sensitised patients<sup>6</sup>. The fibrin radiates in a stellate pattern from a centre of indeterminate nature (Fig. 1). We have analysed this central body.

When we used buffy coats rendered largely devoid of platelets by repeated centrifugal separation, the nucleus of the micro-thrombus appeared as a cell rather than an amorphous mass. Attempts to ascertain the responsible cell by using Ficoll, dextran and albumin separation techniques were unsuccessful because thrombi did not form. But direct centrifugal separation of untreated buffy coat specimens in plastic tubes<sup>7</sup> revealed the upper portion of the buffy coat containing lymphocytes and monocytes to be associated with the induction of the greatest number of thrombi. The lower fraction containing the heavier polymorphonuclear leukocytes showed minimal activity. Rectangular capillary tube thrombi counts<sup>8</sup> and differential counts of smears of comparable buffy coat fractions demonstrated a correlation between the number of thrombi and the number of monocytes or lymphocytes, but not the number of neutrophils, eosinophils or basophils.

The monocyte shows strong surface adherence in contrast to the lymphocyte, and we found that the cells responsible for the thrombi rapidly attached to glass. Buffy coat preparations left in contact with the glass capillary tube or on glass cover slips could be flushed or washed away after 30–60 min at 37 °C, leaving adherent cells which became centres for thrombus formation in the endotoxin-plasma mixture then applied. Furthermore, in preparations made on cover slip slides whereby the slip and slide were forced apart, the central cell had a remarkable set of pseudopods, as evidence of its strong attachment to both surfaces (Fig. 2). Blood left in contact with glass wool for 1 h and then removed failed to produce thrombi.

Fig. 1 Multiple stellate foci of fibrin induced by addition of lipopolysaccharide W ( $10^{-4}$ ) to heparinised blood from patient with vasculitis. The cover slip preparation was incubated 18 h at 37 °C. Central bodies appear to be of indeterminate nature. (Wright-Giemsa.)

Conversely lymphocyte specimens (99% pure) obtained by passing blood through cotton<sup>8</sup> produced no thrombi when exposed to endotoxin.

The cells responsible for the thrombi also proved to be phagocytic. The addition of latex particles<sup>9</sup> (0.011  $\mu$ m, 50  $\lambda$  of  $10^{-4}$  in 1 ml blood) to the regular system led to their endocytosis by the central cell of many of the thrombi (Fig. 3).

Phase and phase interference microscopy with unsealed cover slip preparations showed that the centre of the thrombus was a large cell, generally without refractile granules, and with a reniform, pyknotic or vacuolated nucleus. The cell appearing to be a monocyte had fine filopodia at first. The earliest identifiable pericellular fibrin crystals appeared after 3.5 h. These were short and increased in number and length as time passed. The cell had grey cytoplasm and the nucleus became pyknotic, at time showing karyorrhexis and perinuclear vacuole formation. It sometimes ingested granules. The cell enlarged, became degenerate<sup>10</sup>, with cytoplasm of granular appearance, within 24 h (Fig. 3). At the end of this time, cell identification proved difficult in most cases because of the advanced degenerative changes. The spreading of the central cell could be accentuated markedly by placing a 30-g weight on the cover slip during incubation. Wright-Giemsa (5% acetic acid methanol fixation) or haematoxylin-eosin (Carnoy's fixative) stained the nucleus clearly and showed an eosinophilic cloud at the centre of the thrombus. The myeloperoxidase<sup>11</sup> stain (10% formalin alcohol) showed fine granules consistent with those seen in the monocyte, and neutral red staining showed supravital uptake by some of the central cells. The best stain proved to be the Papanicolaou<sup>12</sup> (95% ethyl alcohol fixation)

because it stained the cytoplasm as well as the nucleus. In the early phase the cytoplasm was green, but after about 6 h it was a distinctive pink orange and later yellow. This seemed to herald the death of the cell, and with this stain each thrombus could be readily spotted by the pinkish centre.

Immunofluorescent staining with fluorescein-isothiocyanate-conjugated anti-human immunoglobulins (Cappel) of cold-acetone-fixed cover slip specimens revealed the central cell stained with  $C_3$  but not with IgG A M D or  $C_2$  or  $C_2$ . This is consistent with the fact that the monocyte has a receptor for  $C_3$  (ref. 13).

The monocyte seems to have a clear cellular role in coagulation. Its ability to induce focal fibrin formation may be related to the observation that human monocytes exposed for 4 h at 37 °C to *Escherichia coli* lipopolysaccharide have a demonstrable coagulant effect in a one-stage coagulation assay<sup>14</sup>. Other non-specific effects of endotoxin include the release of pyrogen, as well as T-cell and colony stimulation<sup>15</sup>. This is in contrast to the specific phenomenon we have observed in patients with vasculitis and various immunological diseases. The fibrin deposition which we have observed around the monocyte may reflect complement activation through the alternative pathway.

As a result of these studies, the monocyte can be viewed as a clot cell, in Yin-Yang contrast to the heparin-containing basophil, an anticlot cell. Study of the monocyte in cell-mediated coagulation promises new information about thrombosis, gram-negative infections and various immunological diseases which involve fibrin deposition. So far the only clinical analogue of our laboratory micro-thrombi may be the stellate

Fig. 2 Single stellate micro-thrombus forming in presence of buffy coat from which platelets have been removed. The unstained fibrin crystals radiate from monocyte, a central dark staining cell with pseudopods. Note lymphocyte at top two polymorphonuclear cells to right and peripheral red cell clusters. (Wright-Giemsa, phase.)

Fig. 3 Single stellate micro-thrombus forming in presence of latex particles. Refractile granules in central cell demonstrate it to be phagocytic. (Unstained, phase.)

fibrin formation observed in the bone marrow of patients with myelofibrosis<sup>16</sup>. The nature of this is not known but the bone marrow monocyte may play a central role.

## Morphological abnormalities in spermatozoa of man and great apes

HUMAN semen has long been known to differ from that of any other mammal in the high proportion of abnormal spermatozoa that it contains<sup>1</sup>. But there has been almost no opportunity to compare human spermatozoa with those of man's closest living relatives, the chimpanzee (*Pan troglodytes*), the pygmy chimpanzee (*Pan paniscus*), the gorilla (*Gorilla gorilla*) and the orangutan (*Pongo pygmaeus*); these are all now endangered species, and the few animals in zoos are not available for experimentation. Recently, workers at the Yerkes Regional Primate Research Center, where all four species are maintained, have perfected a technique for obtaining semen from these rare animals by electroejaculation<sup>2</sup>. Preliminary studies have suggested that marked morphological similarities exist only between the spermatozoa of the gorilla and man<sup>3</sup>. We examined these similarities and differences in more detail, in the hope that spermatozoal morphology might provide some taxonomic clues about our affinities to the great apes.

Measurements of total dry mass were made with an integrated interferometer (Vickers M-86) for a random selection of 50–100 spermatozoa from each individual in each of the five species. In man and gorilla the dry mass distribution was bimodal with two distinct non overlapping peaks, whereas in the chimpanzees and the orangutan it was unimodal (Fig. 2). When arbitrary units of dry mass were used, the mean value of the major peak in man was 730 compared with 960 in the gorilla. In both species the minor peak represented a dry mass approximately twice that of the major peak. These results are similar to those reported for Feulgen-stained human spermatozoa<sup>4</sup>, and suggest that the two groups represent haploid and diploid spermatozoa. The percentage of diploid spermatozoa in man and gorilla was estimated using a larger sample; 21 diploids were found in 2,000 human spermatozoa (1.05%) and 37 in 2,408 gorilla spermatozoa (1.53%). This difference was not statistically significant ( $P > 0.10$ ). Human spermatozoa had the lowest mean haploid dry mass, and gorilla spermatozoa the highest (Table 2). By extracting DNA with trichloroacetic acid and remeasuring dry mass it could be shown that total dry mass was proportional to DNA content in *Homo sapiens*, *Pan troglodytes*, *Gorilla gorilla* and *Pongo pygmaeus* (Fig. 3). Statistical analysis (Table 2) revealed no signi-

**Table 1** Morphology of spermatozoa of man and the great apes

		<i>Homo sapiens</i> (4 individuals)	<i>Pan troglodytes</i> (3 individuals)	<i>Pan paniscus</i> (1 individual)	<i>Gorilla gorilla</i> (2 individual)	<i>Pongo pygmaeus</i> (2 individuals)
Normal	Modal	73.0	95.5	98.0	71.0	98.5
Abnormal	Large head	2.0	0.3	—	2.3	—
	Small head	0.5	—	0.5	0.8	—
	Tapered head	0.3	0.2	—	1.0	—
	Dense-staining	0.6	0.2	0.5	4.5	—
	Vacuolated head	2.4	3.0	1.0	1.3	0.3
	Irregularly shaped	18.4	0.2	—	16.0	0.8
	Multiple heads	0.5	—	—	0.5	—
	Abnormal midpiece	—	0.3	—	0.5	—
	Cytoplasmic droplets	—	—	—	0.3	—
	Immature cells	2.3	0.3	—	2.0	0.5
	Total	100.0	100.0	100.0	100.2	100.1

Semen samples were obtained from normal healthy individuals of proven fertility except for one *Pongo pygmaeus*. In man and in *Pan troglodytes* samples were obtained by masturbation. In *Pan paniscus*, *Pongo pygmaeus* and *Gorilla gorilla* samples were obtained by electroejaculation as described by Warner *et al.*<sup>2</sup>. Semen samples were washed in 0.9% saline and fixed in methanol: acetic acid, 3:1 as described by Sumner<sup>4</sup>. Some of these slides were stained with Papanicolaou's stain and observed under the light microscope: 200 cells were scored per individual and all results of Table 1 are expressed as percentages.

Table 1 shows that there is a similar proportion of 'normal' (modal) and abnormal forms in the ejaculate of men and gorillas; morphologically, the 'normal' forms of the two species are indistinguishable (Fig. 1). Chimpanzee spermatozoa are very different in appearance to human or gorilla spermatozoa, although very uniform in shape; they seem to be identical in all aspects to the spermatozoa of the pygmy chimpanzee. The spermatozoa of the orangutan are morphologically distinct from all the other species, although once again extremely uniform in shape.

Significant differences in dry mass between individuals within a species, but marked differences between species. Although human spermatozoa are morphologically most similar to those of the gorilla, in terms of DNA content they resemble those of the chimpanzees. Gorilla spermatozoa showed the greatest intra-individual variance in haploid DNA content.

Diploid DNA estimates in the somatic cells of the great apes and man have revealed *Homo sapiens*, < *Gorilla gorilla*, < *Pan troglodytes*, < *Pongo pygmaeus*<sup>5</sup> which does not correspond with our haploid estimates of *Homo sapiens* < *Pan troglodytes*,

**Table 2** Comparisons of total dry mass of spermatozoa of the great apes and man

Species	Means	Difference	Approximate 95% confidence limits			
			Assumption A		Assumption B	
			Lower	Upper	Lower	Upper
Chimpanzee-human	810.0–742.3	+67.7	+21.8	+113.6	+41.8	+93.6

Gorilla-chimpanzee	965.2–810.0	+155.2	+98.7	+211.8	+123.0	+187.5
Gorilla-orangutan	965.2–871.6	+93.6	+28.5	+158.9	+56.6	+130.7

The component of variance between individuals within a species is taken to be either 2,000 a.u.<sup>2</sup> (assumption A) or 1,000 a.u.<sup>2</sup> (assumption B). Anovar of haploid dry-mass revealed (1) no significant differences between preparations from the same individual, (2) that the intra-individual variance components for man, chimpanzee and orangutan did not differ significantly (pooled estimate = 4,949.3 with 485 d.f.), but were significantly less than for gorilla (11,606.7 with 197 d.f.). Confidence intervals were constructed using these estimates and taking values of the inter-individual intra-species component to be either 2,000 a.u.<sup>2</sup> (assumption A) or 1,000 a.u.<sup>2</sup> (assumption B). The assumptions correspond to situation in which one individual in 100 can be expected to differ from its species mean by the equivalent of approximately two (A) or one (B) medium-sized chromosomes respectively. The implied degree of aneuploidy suggests that these are overestimates, as are the widths of the corresponding confidence intervals.

**Fig. 1** The spermatozoa of *Pan paniscus* (a); *Pan troglodytes* (b); *Pongo pygmaeus* (c); *Homo sapiens* (d); and *Gorilla gorilla* (e) photographed under Nomarski interference. Scale bar, 10  $\mu$ m.

< *Pongo pygmaeus*, < *Gorilla gorilla*. Man has a diploid chromosome number of 46 compared with 48 in all great apes, and less constitutive heterochromatin and brilliant fluorescent chromatin than the chimpanzee and the gorilla<sup>6</sup>. The overall amount of satellite DNA sequences in man seems to be lower than in the great apes<sup>7</sup>, and presumably all these factors contribute to the low DNA content of human cells.

It has been suggested<sup>8</sup> that the pleiomorphism of human spermatozoa may be a consequence of testicular damage caused by clothing-induced hyperthermia. The fact that the spermatozoa of gorillas living in outdoor cages are just as pleomorphic, and

show an even greater variability in haploid DNA content, tends to refute this argument. Furthermore, the great variability in morphology of human spermatozoa, in contrast to the lack of variability in haploid DNA content, means that morphologically abnormal human spermatozoa are not necessarily genetically defective. The percentage of morphologically abnormal forms is increased in infertile men, however, sometimes reaching very high proportions in cases of abnormal chromosome constitution<sup>9</sup>. It

**Fig. 2** The estimations of total dry mass (TDM) were obtained with a Vickers M-86 integrated microinterferometer. This instrument measures the optical path difference (o.p.d. = refractive index  $\times$  thickness) in arb. units (a.u.). The area of the object (the sperm head only) was selected using an electronic masking system. Measurements were obtained with a X 75 n.a. 1.1 water immersion objective and preparations were measured while immersed in distilled water. All semen samples were treated as specified in the legend of Table 1, except that measurements were done on unstained preparations. 50 cells were measured per individual using two slides (25 measurements in each), except in the gorillas (100 cells; 50 measurements per slide). a, *Homo sapiens*; b, *Pan troglodytes*; c, *Pan paniscus*; d, *Pongo pygmaeus*; e, *Gorilla gorilla*.

**Fig. 3** To test whether TDM is proportional to DNA content, 10 spermatozoa from each of two individuals from each species (except *Pan paniscus*) were measured for TDM. After treatment with 5% trichloroacetic acid at 90 °C to remove DNA, the same spermatozoa were relocated and measured for dry mass after extraction (DMAE). Slides were then stained with Feulgen and the same spermatozoa measured for residual DNA with the M-86 instrument in the microdensitometric mode. Only if no DNA was detected were the DMAE values considered valid. The minimum extraction time needed to remove all DNA was 15 min in man and 30 min in the great apes. The difference between TDM and DMAE represents the dry mass of extracted DNA (DNA-DM). The figure shows mean values of DNA-DM and TDM for each individual, and the estimated least-squares regression line. The latter passes close to the origin, suggesting that proportional changes in TDM are identical to those for DNA-DM. (The line should not of course be interpreted as a valid extrapolation beyond the range of the plotted points.) ○, *Homo sapiens*; □, *Pan troglodytes*; ▽, *Pongo pygmaeus*; ◇, *Gorilla gorilla*.

has even been suggested that fertilisation of a defective egg by diploid spermatozoa will give rise to a hydatidiform mole<sup>10</sup>, and that 40% of triploid embryos are a result of fertilisation of a normal egg by a diploid spermatozoon<sup>11</sup>.

Spermatozoal morphology has been shown to be a useful taxonomic guide in assessing relationships between other species<sup>12</sup>. There is already evidence to suggest that man and gorilla are more closely related than any of the other great apes, as judged by their chromosomal karyotypes<sup>13,14</sup>. Our data on the morphology of their spermatozoa lend further support to this conclusion.

## Continuous growth and differentiation of human myeloid leukaemic cells in suspension culture

ATTEMPTS to develop long-term suspension cultures of human myeloid leukaemic cells have met with limited success. Lymphoblastoid lines carrying the Epstein-Barr virus genome occasionally arise during such attempts but these lymphoid cells originate from contaminating B lymphocytes and not from the leukaemic myeloid cells<sup>1</sup>. A line established from the pleural fluid of a patient with chronic myeloid leukaemia in blast crisis<sup>2</sup> (designated K-562) has no B-cell or T-cell markers<sup>3-4</sup> and does not seem to be of lymphoid origin<sup>4</sup>. Its lack of morphological and histochemical differentiation<sup>2-4</sup>, however, makes it difficult to determine whether these cells are derived from myeloblasts or more primitive stem cells<sup>4</sup>. Another less documented cell line (8261) derived from the peripheral blood of a patient with acute myelogenous leukaemia showed apparent morphological and functional differentiation in agar in the presence of a feeder layer of peripheral blood leukocytes but did not differentiate in suspension culture<sup>5</sup>. Our laboratory previously reported that cultures of differentiating myeloid leukaemic cells can be maintained for several months in suspension culture but only when enriched with conditioned media (CM) from certain monolayer fibroblastic cultures of first trimester whole human embryos (ref. 6 and Ruscetti *et al.* in preparation). We describe here for the first time the derivation from myeloid leukaemic cells of a leukocyte culture that by morphological and histochemical criteria clearly and persistently differentiates along the myeloid series without an exogenous source of conditioned medium.

Peripheral blood leukocytes (designated HL-60) from an adult female with acute promyelocytic leukaemia (clinical details of the case will be published elsewhere) were seeded in T30 plastic flasks (Falcon) at  $1.25 \times 10^6$  cells per flask in 5 ml of RPMI-1640 (GIBCO) medium supplemented with 15% heat-inactivated foetal calf serum (Flow Labs) and gentamicin  $50 \mu\text{g ml}^{-1}$ . The flasks were incubated at 37 °C in a humidified 5%  $\text{CO}_2$  atmosphere. A number of the

**Fig. 1** Initial growth of HL-60 leukaemic leukocytes in suspension culture. After seeding the fresh peripheral blood leukocytes at  $2.5 \times 10^6$  cells per ml, weekly haemocytometer counts were done on aliquots of cell suspensions grown in the presence or absence of conditioned media derived from human embryonic cultures. The dotted lines indicate a culture split. During these early passages, cell counts were done only at fixed intervals and hence do not necessarily indicate the highest count during each passage. TVL is a fibroblast culture of a 12-week human embryo lung. DHL is a fibroblastic culture of a 14-week human embryo lung. ●, TVL-conditioned media; △, DHL-conditioned media; ○, no conditioned media.

**Table 1** Degree of differentiation of fresh uncultured HL-60 cells and cultured cells grown in the presence or absence of DHL-conditioned medium

Fresh cells, obtained by leukaphoresis, were smeared and stained with Wright-Giemsa. Cultured cells at passage 9 were seeded in Falcon T30 flasks at  $2.5 \times 10^5$  per ml on day 0 in the presence or absence of CM. On the days after seeding as noted, the cells were mounted by centrifuging 0.5-ml aliquots of the cell suspension at 500 r.p.m. for 5 min in a Shandon-Elliott SCA-0030 cytospin centrifuge. After Wright-Giemsa staining, differential cell counts were performed. Peroxidase and Sudan black stains were performed according to techniques referenced in the text. NT, not tested.

flasks were supplemented with conditioned media (CM) derived from six different monolayer cultures of various first trimester and early second trimester foetal organs as previously described<sup>6</sup>, while control flasks contained no CM. After three weeks incubation leukocyte growth was noted in flasks containing conditioned media from two different human embryonic fibroblast cultures but not in those without CM or containing other sources of CM (Fig. 1). After splitting the leukocytes and further incubation, cell growth continued only in those flasks containing CM from a single lung embryo culture designated DHL (Fig. 1). After several more weeks, however, the cells continued to grow and differentiate along the myeloid series in the absence of any CM supplements. The cells required foetal calf serum for growth, the optimum concentration being 20% in our culture conditions. When seeded in T30 flasks at  $2.5 \times 10^5$  cells per ml the culture reached a saturation density of  $2.5\text{--}3.0 \times 10^6$  cells per ml in 8–9 d with a doubling time of 55–60 h (Fig. 2).

No evidence of mycoplasma contamination as determined by growth assay in agar<sup>7</sup> has been present. Reverse transcriptase assays of the supernatant culture media<sup>8</sup> as well as thin-section electron microscopy of fixed-cell pellets showed no evidence of type-C viral production or expression.

Most of the cells when stained by the Wright-Giemsa procedure were myeloblasts and promyelocytes with azurophilic granules<sup>8</sup>, but more mature myeloid cells (myelocytes, metamyelocytes, bands and segmented neutrophils)

were also seen (Fig. 3a,b and Table 1). A small percentage of the cells resembled monocytes with blunt pseudopods, pale staining cytoplasm, and convoluted nuclei (Fig. 3c and Table 1). Differential counts of the cultured leukocytes remained quite similar throughout the growth phase of the cells (Table 1). Histochemical studies using stains specific for myeloid cells confirmed the myeloid nature of the cell culture with over 95% of the cells staining positive for Naphthol ASD chloroacetate esterase<sup>9</sup>, Sudan black<sup>10</sup>, and peroxidase<sup>11</sup> (Fig. 3d and Table 1). Although the patient's peripheral blood leukocytes from which this culture was derived contained a significant number of lymphocytes (Table 1), no cells resembling lymphocytes are seen in the present culture. In agreement, T- and B-lymphocyte markers as determined by rosette formation with sheep erythrocytes<sup>12</sup>, and complement-bound antibody-coated erythrocytes<sup>13</sup> respectively, were negative. Tests for Epstein-Barr virus nuclear antigen (EBNA)<sup>14</sup> were also negative. Nucleated red blood cells, present in the patient's peripheral blood cells (Table 1), were not seen in the cultured cells and benzidine stains for haemoglobin<sup>15</sup> were negative. Similar morphological and histochemical differentiation has been noted throughout 30 passages of the cell culture over a period of 9 months.

Chromosome studies of the cultured cells (passage 6) revealed aneuploidy with 27 of 40 metaphases examined showing 44 chromosomes and the remaining metaphases varying from 43 to 47 in number. A modal chromosome number of 44 was also observed in short-term cultures of fresh bone marrow obtained from the patient before therapy (J. M. Trujillo, personal communication). These cytogenetic studies together with the morphological similarity between the HL-60 cells and the patient's leukaemic cells strongly suggest that the cells currently being cultured are of leukaemic cell origin. More detailed cytogenetic studies are in progress to confirm this point.

It is unclear exactly what part the conditioned medium played in the origin of the HL-60 cell culture. Attempts to duplicate the experiment using frozen stocks of the patient's fresh uncultured peripheral blood leukocytes were not successful. Also the DHL-conditioned medium failed to stimulate growth of samples of peripheral leukocytes obtained from 18 different myelogenous leukaemia patients, although none of these was of the promyelocytic variant. With the readdition of CM to the growing HL-60 culture, no changes in morphological appearance, histochemical staining, degree of differentiation (Table 1), growth rate, or saturation density were noted. The initial growth of the HL-60 cells only in those flasks containing CM could have

**Fig. 2** Continued growth of HL-60 cells in the absence of conditioned medium. The dotted lines indicate a culture split.

**Fig. 3** Cytological and histochemical characteristics of HL-60 cells cultured in the absence of conditioned medium. *a*, Mature polymorphonuclear leukocyte surrounded by myeloblasts and promyelocytes containing cytoplasmic granules. Wright-Giemsa stain ( $\times 1,000$ ). *b*, Two promyelocytes with prominent cytoplasmic granules together with three metamyelocytes undergoing nuclear differentiation. Wright-Giemsa stain ( $\times 1,000$ ). *c*, Single cell with blunt pseudopods, pale staining cytoplasm, and convoluted nucleus resembling a monocyte. Wright-Giemsa stain ( $\times 1,000$ ). *d*, Positive myeloperoxidase stain which histochemically confirms the myeloid morphological appearance of the cells ( $\times 1,000$ ).

been fortuitous, although further studies are required to assess the interaction of the DHL-conditioned medium with the HL-60 cells as well as with leukaemic cells from other patients with promyelocytic leukaemia.

The presence of a cell culture that clearly differentiates along the myeloid series apparently without the addition of an exogenous source of inducer raises some intriguing questions regarding myelopoiesis in normal and leukaemic cells. It is generally assumed that normal stem cells will differentiate along the myeloid series only when influenced by specific microenvironmental factors, which may be similar to granulopoietin or colony-stimulating factor (CSF)<sup>16</sup>. Previous reports have described differentiation of certain murine and human myeloid leukaemic cells in both suspension<sup>6,17</sup> and agar<sup>18,19</sup>, but only in the presence of appropriate conditioned media or of a 'feeder layer' of peripheral blood leukocytes. Hence the HL-60 myeloid cell culture described here seems to be unique in its ability to proliferate and differentiate without an exogenous source of inducer. These cells may indeed be autonomous with respect to differentiation. It is conceivable, however, that a certain subpopulation of these cultured cells is secreting factors regulating proliferation and differentiation of the remaining cells. Our investigations are directed towards isolating such a subpopulation as well as determining the response of the HL-60 cell culture to the known inducers of myeloid differentiation<sup>20</sup>.

We thank Dr C. Tai of Biotech Laboratories, Rockville, Maryland who performed the initial cytogenetic studies on the HL-60 cell culture.

## Non-random chromosome gains in human lymphoblastoid cell lines

HUMAN lymphoblastoid cell lines derived from the peripheral blood lymphocytes of healthy donors are commonly diploid when examined in the early months after establishment but acquire chromosome abnormalities on prolonged culture. Other lines, notably those derived from Burkitt's lymphoma tissue, may display chromosome aberrations from the outset<sup>1-5</sup>. A partial translocation 8q-14q+ has been demonstrated in the majority of Burkitt lymphoma-derived lines<sup>6</sup>, and data on the karyotypes of some human tumours suggest that non-random gains and/or losses of chromosomes may be a feature, in particular, of certain leukaemias and lymphomas<sup>7-13</sup>. As the emergence of an aneuploid clone from a previously diploid lymphoblastoid line may be associated with other changes suggesting the development of a more 'malignant' phenotype<sup>14</sup>, it is relevant to compare the chromosome aberrations detected in such lines with the human tumour data. We have therefore undertaken a study of banded karyotypes of eighty EB virus-carrying human lymphoblastoid lines. The first stage of this analysis is concerned only with gains and losses of whole chromosomes or chromosome arms and the data presented here establish that, considering all the lines together, there have been non-random gains of five autosomes (numbers 3, 7, 8, 9 and 12) and of the sex chromosomes.

Most of the cell lines studied were originally established in this laboratory and all had been maintained in this laboratory for at least 6 months. The derivation of the lines and their 'age' *in vitro* are set out in Table 1. Chromosome analysis was carried out on photographs from quinacrine-stained metaphase spreads<sup>15</sup>. (A more detailed examination of chromosome breaks and translocations in these lines is in progress making use of G and R banded, in addition to quinacrine stained, preparations.) In most instances, serial studies have been made on the lines and the emergence of new chromosomally marked clones has been traced over a period of up to 6 yr<sup>3</sup>. Aberrations detected in only a single cell from a given preparation were ignored while any which recurred in successive clones (identified by additional chromosome markers) from a given line were scored only once for that line. Where a lymphocyte donor had a constitutional chromosome abnormality (Trisomy 21 or XXY, for example) the corresponding abnormality in the derived lymphoblastoid line was not scored as an aberration. There was rarely any difficulty in recognising duplication or deficiency of a whole chromosome or chromosome arm and in establishing that such a marker characterised at least a significant proportion of the cells of a given line. The number of photographs in which a particular aberration could be identified was usually between 6 and 20.

The findings are presented in Fig. 1: 36 lines contribute to these data since eight lines listed as 'aneuploid' in Table 1

Table 1 Lymphoblastoid cell lines studied

Derivation	No. of lines	Age < 1 yr		Age > 1 yr	
		Diploid†	Aneuploid	Diploid	Aneuploid
No lympho-reticular malignancy‡	55	23	2	5	25
Lympho-reticular malignancy§	17	1	0	2	14
Burkitt's lymphoma	8	0	0	0	8
Total	80	24	2	5	49

\**In vitro* 'age' at latest karyotype analysis. Most lines have been followed serially since establishment.

†Status at latest karyotype analysis.

‡Includes lines established from cord bloods, healthy adults, patients with infectious mononucleosis, carriers of constitutional chromosome aberrations (see text), and patients with cancer of bladder or gastrointestinal tract.

§Includes lines from patients with acute and chronic leukaemias, myelofibrosis, and Waldenstrom's macroglobulinaemia. Excludes Burkitt's lymphoma.

had internal rearrangements without substantial gains or losses and a further seven (including three from Burkitt's lymphoma) were near-tetraploid.

It is evident that gains occur much more frequently than losses. In fact apparent absence of a chromosome has always been associated with the presence of one or more unidentifiable abnormal chromosome whose total length is at least equal to that of the material otherwise unaccounted for. The only exception to this rule is the Y chromosome which was lost from two lines. The residual stemline in one is 45,X. The other was derived from a 47,XXY Klinefelter

syndrome patient and the two X chromosomes remain. In the same line there were gains of chromosomes 3, 8, 11 and 12.

Analysis of the total data shows that trisomy or partial trisomy for five autosomes and the sex chromosome pair occurs with remarkable frequency. Out of a total of 66 additional chromosomes or chromosome arms, more than two-thirds (47) are accounted for by only 6 of the 23 pairs, numbers 3, 7, 8, 9, 12 and X+Y (treating the sex chromosomes as one pair). On the null hypothesis that all pairs contribute equally to the additional chromosomes or chromosome arms, it can be shown that the probability that six pairs account for at least two-thirds of them is less than  $10^{-6}$ . No single line is trisomic for all of these chromosomes but in four cases trisomy 12 is associated with an extra number 3, 8 or 9 and in one other line (mentioned above) there is trisomy for three of the five autosomes.

The cultures examined include multiple (two to four) lines derived from the blood lymphocytes of each of seven donors. Given that the distribution of extra chromosomes in the total series of cultures is non-random, there seems to be no particular tendency for identical aberrations to recur in multiple lines from a single donor. Eight other lines were grown from the blood lymphocytes of patients with constitutional chromosome aberrations (45,X, 47,XXY, 49,XXXXY, 47,XYY, trisomy 21 and balanced autosomal translocations). As a group they have shown no greater or lesser tendency to develop further aneuploidy *in vitro* than lines from chromosomally normal donors.

Trisomy 7 has been noted in at least two fresh Burkitt lymphoma biopsies and in previously-described Burkitt lymphoma cell lines<sup>3</sup>. Our data support the view that this aberration has a particular association with Burkitt's lymphoma since trisomy 7 (in one case partial) was found in four of the five Burkitt lines which could be scored, Daudi, Namalva, Jijoye and RAJI. Three other lines, EB<sub>1</sub>, EB<sub>2</sub> and EB<sub>3</sub> are near tetraploid and rather variable in chromosome complement while EB<sub>1</sub> has four large abnormal chromosomes any of which may include a substantial part of an additional number 7. Our results show, however, that trisomy 7 is not restricted to Burkitt-derived lines and the same aberration has also been reported in two lymphosarcoma biopsies, in lymphoblastoid lines from lymphosarcoma and Hodgkin's disease and in cultures of melanoma tissue<sup>6-8</sup>.

Trisomy 8 has been observed with striking frequency in the acute phase of chronic myeloid leukaemia, in acute non-lymphatic leukaemia, in polycythaemia vera and in other myeloproliferative disorders. In all of these conditions except myeloid leukaemia, trisomy 9 also occurs more often than would be expected if extra chromosomes were distributed at random<sup>9-12</sup>. There is thus some suggestion of concordance between specific chromosome gains observed in cultured human lymphoblastoid lines and in malignancy, particularly when it affects the lympho-reticular system. On the other

Fig. 1 Cumulative chromosome gains and losses in 36 lymphoblastoid lines. Each line trisomic for a given chromosome is recorded as a full circle to the left of that chromosome number; monosomy is indicated by a full circle to the right. Lines are grouped as in Table 1. Open symbols, lines from patients with no lymphoreticular malignancy; cross-hatched symbols, lines from patients with lymphoreticular malignancy, not Burkitt's lymphoma; filled symbols, Burkitt's lymphoma-derived lines. Partial trisomy or monosomy indicated by upper semicircle (short arm) or lower semicircle (long arm). In addition to gains or losses indicated, there were 19 unidentifiable abnormal chromosomes in the total sample, nine from four Burkitt's lymphoma-derived lines, six among three lines from patients with non-Burkitt's lymphoma lymphoreticular malignancy and one each in four other lines.

hand, trisomy 3 or 12 do not seem to be characteristics of any human neoplasms reported so far and in acute leukaemias loss rather than gain of one chromosome seems to be the norm<sup>11,12</sup>. Furthermore, there are several examples of non-random chromosome gains or losses in particular human tumours which do not correspond to the changes observed in our material<sup>10-13</sup>.

The phenomenon of non-random chromosome gains in cultured human lymphoblastoid lines is established by this study. Its significance may be tested by planned experiments in xenotransplantation involving diploid and aneuploid cells from the same lines.

We thank Professor M. A. Epstein (Bristol) for provision of cell lines, Mr Norman Davidson for photographic work, Mr Andrew Carothers for statistical analysis and Miss Karin Buckton for useful discussions.

## Essential role of surface-bound chemoattractant in leukocyte migration

MANY chemotactic factors, usually proteins or peptides, have been isolated and studied, but little is known about the basic mechanism of leukocyte migration. This movement is termed chemotaxis if its direction is determined by substances in the cells' environment<sup>1</sup>. The chemotactic agent is assumed to convey information to the leukocytes by interaction with receptors. The subsequent sequence of events thus triggered in the cells is unknown but metabolic changes such as activation of an esterase have been reported as occurring as the cells move forward (for review see ref. 2). A role for surface-bound chemoattractant in cell locomotion was suggested by the observation that mouse fibroblasts move preferentially from substrates of lesser to those of greater capacity to bind to cells<sup>3,4</sup>. A close relationship has also been suggested between the mechanism of chemotaxis and phagocytosis<sup>5</sup>. In both cases cells form protrusions of motile membrane which carry receptors for either chemoattractants or opsonins. For example, such membrane protrusions have been shown to bind bacteria and also to attach to opsonised particles, through Fc receptors to IgG-Fc or through C3 receptors to C3 fragments. Once initial contact is established during phagocytosis further membrane segments bind, enabling the cell to creep around the bacterium until it is ingested. We report here that using casein, a chemotactic agent in a standard chemotaxis assay<sup>6</sup>, we have found that binding of casein to a solid substratum is essential for its attracting capacity.

Two sets of microporous cellulose nitrate filters were prepared. To the first set <sup>125</sup>I-casein (casein, from Merck, Darmstadt)

was dissolved in NaOH and adjusted to pH 7.35 by HCl) was bound in a dose-dependent manner (Fig. 1) by incubating the filters for 10 min at room temperature with casein concentrations ranging from 0.5 to 6 mg ml<sup>-1</sup>. Unbound casein was removed by placing the filters in a suction device and washing with 25 ml of Hank's balanced salt solution (HBSS), after which no additional <sup>125</sup>I-casein could be eluted. The second set of filters was treated with HBSS only. To test for surface-bound chemotactic factors, the filters were placed in modified Boyden chambers<sup>7,8</sup>. The upper compartments were filled with a suspension of 2 × 10<sup>6</sup> guinea pig peritoneal granulocytes, which were collected 18–22 h after injection of glycogen (0.1%, w/v), and the lower compartments were filled with either HBSS (casein-treated filters) or increasing amounts of casein (HBSS-treated filters). In the latter case, the casein concentrations in the lower compartments were the same as those used to prepare the casein-treated filter. After incubation for 90 min at 37 °C the distance migrated by the granulocytes into the filter was measured.

**Fig. 1** Uptake of casein by cellulose nitrate filters. Cellulose nitrate filters (3 µm pore size, 25 mm diameter, type AE97, Schleicher & Schüll) were incubated (10 min at room temperature) in 2 ml of solutions containing increasing concentrations of <sup>125</sup>I-labelled casein. The filters were then placed in a suction device (type FN 023/0, Schleicher & Schüll) and 25 ml of HBSS were passed through the filters. Based on the amount of radioactivity bound per filter, the total amount of casein attached to the filter was determined.

With casein concentrations of approximately 3 mg ml<sup>-1</sup>, almost identical migration distances were obtained (Fig. 2) whether the filters were preincubated in casein solutions (first set) and used without further addition of casein to the Boyden chamber, or whether the filters were initially free of casein (second set) and used in the test by adding casein to the lower compartment of the chamber. At casein concentrations of 0.5 and 1 mg ml<sup>-1</sup> the granulocytes in the first set of filters were found to have migrated slightly longer distances than the granulocytes in the second set of filters. Concentrations of casein higher than 3 mg ml<sup>-1</sup> led to opposite results for the two sets of filters. While with the first set of filters a slight increase in migration distance was observed (Fig. 2), the second set yielded a continuous decrease of the migration distance in parallel with the increase in casein concentration in the lower compartment. This reduction distance can therefore only be attributed to the presence of casein which was not bound to the substratum. These experiments were repeated 10 times and showed a clear reproducibility. If purified casein was used for the experiments instead of the commercially available casein, similar results were obtained with filter-bound casein whereas in the standard chemotactic assay higher casein concentrations were required to affect inhibition of migration (data not shown).

To confirm the role of surface-bound chemoattractant, filters soaked with a solution of 2.5 mg <sup>125</sup>I-casein per ml and washed in HBSS, were incubated for 20 min at 37 °C with solutions of

**Fig. 2** Effect of filter-bound casein on leukocyte migration. Cellulose nitrate filters prepared as described in the legend to Fig. 1 were used in the Boyden chamber with 1 ml of  $2 \times 10^6$  guinea pig peritoneal granulocytes in the upper compartment and HBSS in the lower compartment ( $\square$ ). For controls, filters preincubated in HBSS instead of casein were used with solutions of increasing casein concentration in the lower compartment ( $\bullet$ ). Along the abscissa the casein concentrations are indicated which, in the case of the first set of filters ( $\square$ ), were present during the preincubation and, in the case of the control filters ( $\bullet$ ), during the actual migration test.

increasing concentrations of papain ( $1 \times 10^{-8}$ – $1 \text{ mg ml}^{-1}$ ) and the papain-induced release of casein from the filter was followed (Fig. 3). It was found that increasing concentrations of papain led to increasing release of radioactive material and, simultaneously to decreasing migration distances. In control experiments it was shown that preincubation of the filter with papain, followed by washing with HBSS had no effect on the migration of the leukocytes towards the casein in the lower compartment. Thus we could exclude the possibility that any papain remaining in the filters after the washing procedure would interfere with migration of the cells.

These results suggest that filter bound casein has the essential role in the promotion of casein-induced leukocyte migration, and that casein in free solution may even be inhibitory. Whether this is due to receptor blockade or to toxic effects is not clear. From our experiments with purified casein, the latter possibility seems to be more likely. It is also important to establish whether other chemoattractants behave like casein. If this is a general characteristic, cells responding to a chemotactic stimulus could be envisaged as creeping along by holding on to surface-bound chemoattractants with special receptors or receptive

sites. Binding of fluid phase reagents to the same cell receptors might result in blocking the interaction of these receptors with the surface-bound material. Also, fluid-phase reagents might bind first to the cell receptors, and thereby promote secondary binding to a nearby surface, or they might stimulate cells to secrete factors with functional characteristics similar to those of casein. This is not so far fetched, as we have observed that supernatants obtained by incubating leukocytes for 30 min at  $37^\circ\text{C}$  in HBSS contain substances which, like casein, modulate filters so that they now can induce the locomotion.

According to this view, leukocytes migrating *in vivo* would be crawling along tissue surfaces coated with chemoattractants. By analogy with fibroblasts<sup>3,4</sup> the cells would migrate to where there was a greater amount of attractive substances fixed per unit surface area which would coincide with a tighter binding. This is supported by preliminary experiments with filters to which casein was not attached uniformly but with an increasing concentration from one side to the other (unpublished results). This movement would only be possible if unoccupied receptors could be made available continuously at the leading edge of the cell or on the protrusions actively reaching out from the cell body searching for sites of attachment. Therefore the cells must either be able to synthesise new receptor sites or to re-use the already existing ones. Harris's concept<sup>9</sup> that the surface proteins in moving cells continuously circulate within the membrane from the front of the cell to its trailing end, then become internalised and, after a hypothetical passage through the cytoplasm, become incorporated again into the front section of the cell, seems to be most attractive. It is possible that proteolytic activity might be involved in freeing the receptors from the bound substance, since chemotactic factors are known to induce release of lysosomal enzymes<sup>10–12</sup>.

We thank Dr P. Henson for helpful discussion and Miss Jutta Scholtka and Miss Helga Braun for technical assistance. The work was supported by the DFG (SFB 107 Di A5 and Ti 63/5).

**Fig. 3** Reduction of casein-dependent leukocyte migration by pretreatment of the  $^{125}\text{I}$ -casein-coated filters with papain. Filters incubated in a solution of  $2.5 \text{ mg } ^{125}\text{I}$ -casein per ml and washed in HBSS were incubated 20 min at  $37^\circ\text{C}$  with solutions of increasing concentrations of papain (abscissa) containing appropriate amounts of cysteine. Then the filters were washed and the release of radioactivity was determined ( $\bullet$ ). The same filters were tested for leukocyte migration ( $\diamond$ ).

## Membrane-bound H-2 and H-Y antigens move independently of each other

ON exposure to foreign antigens, mouse T lymphocytes can be stimulated to mature into cytotoxic cells able to kill target cells carrying these antigens<sup>1–4</sup>. Killing is restricted to cells bearing, in addition to the foreign antigen, the same H-2K or H-2D antigens as the stimulating cell. Cells bearing different H-2 antigens are not killed. To kill a lymphocyte, two recognition steps are necessary: one involving the foreign antigen and another involving H-2

antigens. This associative recognition has been demonstrated for many antigens and must be considered a general phenomenon. Two opposing views have been proposed to explain the associative recognition<sup>1</sup>. According to the altered-self hypothesis, the antigen links up on the cell membrane with H-2 molecules and the complex of antigen plus H-2 is then recognised by a single receptor on a T lymphocyte. According to the dual recognition hypothesis, each T lymphocyte has two receptors, one for the antigen and the other for H-2, and it is the combination of the two receptors on each cell that is responsible for the associative recognition. The strongest evidence in favour of the first hypothesis is the report of a physical association between antigens and H-2 (see, for example, ref. 6). The link-up of the antigen to H-2, however, might not be related directly to the associative recognition, but rather reflect some other phenomenon in the membrane, in which case there should be examples of associative recognition without a linkage between the antigens. We present evidence for such an association.

Associative recognition has been demonstrated for H-Y, the male-specific antigen. Gordon *et al.*<sup>3</sup> showed that C57BL/10 female mice, when primed to H-Y, develop cytotoxic effector cells which are able to lyse male target cells carrying the same H-2 haplotype as the females (H-2<sup>b</sup>). According to the altered-self hypothesis, the H-Y and H-2 should form supramolecular complexes that, in the membrane, redistribute together when exposed to either H-Y or H-2 antibody. We tested this assumption as follows. We incubated C57BL/6 (H-2<sup>b</sup>) male thymocytes at 37 °C with either anti-H-2K.33 or anti-H-2D.2 (or both sera) which react with private antigens controlled by the H-2K<sup>b</sup> and H-2D<sup>b</sup> alleles of the H-2<sup>b</sup> haplotype, respectively. We then stained the cells with rabbit anti-mouse IgG (RAMIG) serum conjugated with tetramethylrhodamine isothiocyanate (TRITC)<sup>7</sup>. In these conditions most of the H-2 molecules were in a cap at one pole of the cell. We then applied to these capped cells the mouse anti-H-Y serum at 0 °C and

determined the distribution of the H-Y antibodies using goat anti-mouse IgG (GAMIG) conjugated with fluorescein isothiocyanate (FITC). If H-2 and H-Y were associated, then capping of H-2 should cause capping of H-Y. In this case, no H-Y should remain outside the H-2 caps (the red and green fluorescence of TRITC and FITC, respectively, should overlap and be seen only in the cap with the remainder of the cell not staining at all). If, on the other hand, H-2 and H-Y were not physically associated, there should be a red cap of H-2 and diffuse green staining of H-Y (and—in cases where the GAMIG antibodies find places on the cap unoccupied by the RAMIG—possibly also green cap).

The results are shown in Table 1. When B6 cells were first incubated at a capping temperature (37 °C) with anti-H-2K.33 serum, about one-half stained specifically for the H-2K.33 antigen and in all of them the red TRITC stain had gathered in caps. (The thymocyte population is heterogeneous in terms of the degree of H-2 antigen expression; the weakly H-2 positive cells were classified as negative in the staining conditions used in this experiment.) When these cells were re-exposed to the same antiserum (anti-H-2K.33) in non-capping conditions, no additional staining could be picked up by the FITC-GAMIG antiserum. On exposure to anti-H-2D.2 or to anti-H-Y serum, however, 50 and 60% of the cells, respectively, picked up diffuse green fluorescence. These percentages closely correspond to the percentages of cells reacting with the two antisera in a situation where anti-H-2K.33 was replaced by a medium. We conclude, therefore, that capping of H-2K.33 did not result in any significant capping of H-2D.2 or H-Y. Similar results were obtained when the anti-H-2D.2 serum was used first and the anti-H-2K.33 and anti-H-Y sera second. In this instance the three antigens again redistributed in the cell membrane independently of one another. When the cells were incubated at 37 °C with a mixture of anti-H-2K.33 and anti-H-2D.2 sera, virtually no cells with diffuse green fluorescence were found after re-exposure at

**Table 1** Redistribution of H-2 and H-Y antigens after treatment of C57BL/6J male thymocytes with corresponding antisera

First treatment (37 °C)	Second treatment (0° to 4 °C)	No. of cells counted	% Of cells stained with TRITC Redistributed	% Of cells stained with TRITC Diffuse	% Of cells stained with FITC Redistributed	% Of cells stained with FITC Diffuse + caps

Thymuses were removed without parathymic lymph nodes. Cell suspension was prepared by pressing the organ through a stainless-steel sieve (50-mesh) into Eagle's essential medium (GIBCO) containing 20% heat-inactivated foetal calf serum and cycloheximide (100 µg ml<sup>-1</sup>, pH 7.4–7.6 (hereafter referred to as 'medium')). Cells were washed twice and resuspended in the medium. For the first treatment, aliquots of thymocyte suspension containing 5 × 10<sup>6</sup> cells were distributed into small tubes and centrifuged. Alloantiserum or medium, 50 µl, was added to the packed cells, resuspended cells were incubated for another 30 min at 37 °C. After one washing, incubations with alloantiserum (medium) and TRITC-RAMIG were repeated once more. For the second treatment, the cell suspensions were divided into four tubes and transferred to an ice bath. The packed cells were incubated for 30 min with alloantiserum or medium, and, after one washing, with FITC-GAMIG for 30 min. After the last incubation, cells were washed three times at 0° with medium and fixed with 1% paraformaldehyde in phosphate buffered saline. A drop of the cell suspension was placed on microscope slide, allowed to dry, and mounted in 90% glycerol. The slides were scored using a Leitz Ortholux II fluorescence microscope equipped with a Ploem epi-illumination system. Antisera were as follows. Anti-H-2K.33: (B10.D2 × A)F<sub>1</sub> anti-B10. A(5R); anti-H-2D.2: [C3H/HeJ × B10.D2(R107)]F<sub>1</sub> anti-B10. A(4R); anti-H-Y: C57BL/6J anti-C57BL/6J. The H-2 sera were produced as described elsewhere<sup>8</sup>; anti-H-Y serum was prepared by inoculating C57BL/6 females every 2 weeks with 25 × 10<sup>6</sup> C57BL/6J male spleen cells i.p., and the antiserum was obtained 10 d after the seventh inoculation. The activity of H-2 and H-Y antisera was determined by cytotoxic test against lymphocytes<sup>9</sup> and spermatozoa<sup>10</sup>, respectively.

\*In all 'second treatments' cells were incubated with FITC-GAMIG after initial incubation with alloantiserum or medium.

0 °C to either of the two antisera separately: all the detectable H-2 antigens were capped. But the cells still stained diffusely after exposure to H-Y antiserum. The percentage of the cells with green diffuse fluorescence was once again comparable to that in the aliquots treated first with medium and then with anti-H-Y serum. We conclude, therefore, that complete capping of H-2 antigens has no detectable effect on the distribution of the H-Y antigen: the two types of antigen apparently are not linked in the cell membrane. This conclusion, however, requires at least two qualifications. First, it is possible that while the majority of H-Y molecules are not associated with H-2, a small number are; the latter might not be detected by our method. Second, H-2 and H-Y molecules might be associated before the exposure to antibodies and the antibody might break such bonds. Assuming that neither of these two qualifications applies, one has to conclude either that the H-Y associative recognition is a special case and its mechanism is different from associative recognition of other antigens, or that linkage between the antigen and H-2 is not required for the recognition to occur. Since we find little evidence to support the former possibility, we favour the latter. Our finding does not, however, resolve the dispute between altered-self and dual recognition. It is possible, for instance, that what is needed for recognition to occur via a single receptor is that the H-2 and H-Y (or other antigens) come close to each other in the membrane. With the membrane being in a semifluid state, there is ample opportunity for such an event to occur.

We thank Dr Rolf Zinkernagel for discussion. The work was supported by grants from the USNIH.

## Rate of offset of action of slow-acting muscarinic antagonists is fast

ATROPINE generally behaves as a competitive antagonist of acetylcholine (ACh) at muscarinic receptors<sup>1–9</sup> but its onset and offset of action are slow. It has been suggested that the rates of onset and offset of atropine blockade are determined by the rates of binding to and dissociation from the ACh receptor<sup>4,5,10</sup> a suggestion which at first sight seems incompatible with competitive blockade. An alternative explanation is that access of antagonist (in contrast to agonist) to the receptors, and escape from their vicinity on washing, is delayed or impeded in some

way<sup>11–15</sup>. Experiments in which atropine is applied to a small superficial region of the tissue would seem to offer the best chance of reducing this access factor to a minimum and help in deciding which explanation for atropine's slow action is correct. The iontophoretic method presents itself as the method of choice, but until now, no such experiments have been carried out. The results of this type of experiment carried out on smooth muscle are described here. They reveal that the rate of offset of blockade by slow acting muscarinic antagonists can be more than ten times faster than that seen when antagonists are applied by their addition to the solution bathing (or perfusing) the muscle.

The iontophoretic application of ACh (typically using a 50-nA, 2.5-nC pulse) usually elicited a monophasic depolarisation with a latency of 0.1–1 s (Fig. 1) although bi- and polyphasic responses were also observed<sup>18</sup>. The sensitivity to ACh was tested every 16–20 s, or occasionally every 8 s, and in stable preparations the response varied little. Three muscarinic blocking agents were studied for their effects on the ACh (or carbachol) response. These were: atropine sulphate, (2-benzilyloxyethyl) diethylmethyl ammonium iodide (the diethyl analogue of lachesine<sup>19</sup>, DE lach) and the partial agonist hexyl trimethyl ammonium iodide (hexyl TMA)<sup>2,14</sup>. DE lach resembles lachesine except that one of the quaternary nitrogen methyl groups is replaced by an ethyl group. This marginally increases its potency<sup>19</sup>. The release of any one of these substances from the other barrel of a double-barrelled iontophoretic pipette could reduce or abolish the response to ACh or other muscarinic agonist (Fig. 1). If no further blocking agent was applied, the responses recovered their former size at a rate which was different for each drug.

**Table 1** Rate of offset of blockade by muscarinic antagonists

Antagonist	No. of experiments	Time (s)*		$K_{off}(s^{-1})$
		Half recovery	Full recovery	
Atropine	14	62 ± 15	216 ± 24	~ 11 × 10 <sup>-3</sup>
DE lach	10	21 ± 1.6	46 ± 2.2	~ 34 × 10 <sup>-3</sup>
Hexyl TMA	1	9	25	~ 77 × 10 <sup>-3</sup>

\*Mean ± s.e.m.

Pulses of antagonist were chosen which produced initially 90–100% reduction in the response to ACh or other agonist. To obtain a quantitative measure of the speed of offset of antagonism, the times from first re-appearance of the response to 50% recovery or to full recovery, were measured in a number of experiments (Table 1). The effects of an atropine or DE lach pulse sufficient initially to nearly or completely abolish the response to ACh were completely absent on average after about 3.5 min and 45 s,

**Table 2** Summary of rate constants of offset of antagonist action as measured by various workers

Antagonist	$K_{off}(s^{-1})$	Tissue	Reference
Atropine	0.3 × 10 <sup>-3</sup>	Atria	12
	1.3 × 10 <sup>-3</sup>	Perfused heart	12

DE lach	34 × 10 <sup>-3</sup>	Taenia	This work

respectively, and recovery to half size was achieved at about 1 min and about 20 s.

To facilitate comparison with the work of others, the time to half-recovery has been multiplied by the factor 1.44 to obtain the rate constant of offset of antagonism ( $K_{off}$ ), assuming an exponential decline of occupancy by blocking agent and a linear relationship between response and agonist dose<sup>12</sup>. It is doubtful if these assumptions are strictly justified but the error involved is insignificant when compared with the rates of offset of blockade

**Fig. 1** Block of response to iontophoretic ACh by an iontophoretic pulse of DE lach and its subsequent recovery. *a*, Lowest trace (10 mV calibration). Depolarisation caused by the stimulation of the muscarinic receptors of smooth muscle by ACh (3.6 nC) released as indicated by the top iontophoretic monitor trace (200 nA calibration). Membrane potential was recorded intracellularly by microelectrode within 25  $\mu$ m of the point of application of ACh from one barrel of a twin-barrelled iontophoretic pipette with spacer<sup>16</sup>. The membrane potential before each application of ACh was first hyperpolarised by passing inward current (middle trace and 10  $\mu$ A calibration) to prevent spiking and contraction. This part of the record is shown in *a* but is omitted in subsequent ones. Later responses to ACh were obtained at 8 s, *b*; 24 s, *c*; 40 s, *d*; and 56 s, *e* after DE lach (8 nC, not shown) which was applied from the other barrel of the iontophoretic pipette. The preparation was a narrow longitudinal strip cut from the longitudinal muscle of the guinea pig caecum (taenia). The region of active muscle was further reduced by creating a 'node' of active muscle, perfused with isotonic physiological salt solution (composition given in ref. 17) at 35  $^{\circ}$ C, between two streams of de-ionised sucrose solution in a type of double sucrose-gap apparatus described previously<sup>17</sup>.

given in the literature (Table 2), using muscle preparations bathed or perfused with solution containing the blocking agent. In general, previous measurements of the rate of offset of blockade are at least ten times slower (range 6–49) which argues strongly that in experiments described by others it is factors other than just dissociation from the receptors, which determines the rate of offset of blockade.

**Fig. 2** Time course of onset and offset of blockade by DE lach pulse (16 nC) constructed by combining measurements of the percentage reduction in ACh responses by some 39 separate DE lach pulses placed with varying time relationships to the ACh pulses. Standard errors ( $\pm$ ) are shown only for those points which are the mean of measurements made on at least five responses. The lines (fitted by eye) are exponentials ( $\tau = 3.7$  and 13 s). Notice that maximum block (about 85%) by DE lach occurs some 5–10 s after release of DE lach from the pipette.

The rate of offset of blockade by hexyl TMA was estimated by means of a series of applications of hexyl TMA placed in varying time relationships to agonist responses elicited every 20 s, and the percentage reductions in agonist response measured. Combination of the results obtained with 17 separate applications of hexyl TMA in one experiment enabled it to be estimated that full recovery took place within about 25 s, and half-recovery within 9 s of application of a blocking pulse of hexyl TMA. The blocking action of hexyl TMA could only be demonstrated with large pulses (50–100 nC). Smaller pulses (10–20 nC) were observed to have only agonist action.

The simultaneous release of blocking doses of hexyl TMA and a strong agonist abolished the response to agonist immediately. This was not the case with DE lach. Figure 2 shows the time course of onset of DE lach blockade calculated from the results of 39 separate DE lach applications to one preparation where the timing of blocking pulses of DE lach was varied with respect to regular ACh pulses. Blockade by DE lach took some 5–10 s to become maximal and then offset of blockade commenced. The onset of blockade by atropine could not be studied in detail because it was generally found necessary to pass iontophoretic current for several seconds to release sufficient atropine to produce blockade.

The much greater rate of offset of antagonism by atropine and DE lach seen in the present experiments suggests that the muscarinic ACh receptors involved in the depolarising response may be relatively superficially placed, so that escape of antagonist from the immediate vicinity of the receptors does not determine the rate of offset of blockade. In such a case, the rates of offset of antagonism ( $K_{off}$ ) seen here give lower limits for the dissociation rate constants ( $k_2$ ) for the binding of atropine, DE lach, and hexyl TMA of  $11 \times 10^{-3}$ ,  $34 \times 10^{-3}$ , and  $77 \times 10^{-3} \text{ s}^{-1}$  (Table 1). If it is assumed that the equilibrium constants ( $k_2/k_1$ ) for atropine and DE lach are  $1.1 \times 10^{-9}$  and  $1.4 \times 10^{-9} \text{ M}$  (refs. 4, 5 and 13) then the association rate constants ( $k_1$ ) will be  $10^7$  and  $2.4 \times 10^7 \text{ M}^{-1} \text{ s}^{-1}$  respectively. These association rate constants are approaching the theoretical maximum for enzyme-substrate reactions of about  $10^8 \text{ M}^{-1} \text{ s}^{-1}$  (ref. 21). This supports the hypothesis that the rate of offset of antagonism observed in these experiments may be

giving for the first time a true indication of the rate of dissociation of antagonist from the muscarinic receptor.

This work was supported by the MRC and owes much to discussions with Professor H. P. Rang and Dr D. Colquhoun.

## Glutamate as transmitter of hippocampal perforant path

CERTAIN experimental manifestations of plasticity, such as habituation<sup>1–3</sup> and long-term potentiation<sup>2,4–6</sup>, can be readily demonstrated at the perforant path-granule cell synapse in the fascia dentata, and these adaptations are believed to have behavioural counterparts. The perforant path-granule cell synapse may thus serve as a model for investigating the simplest components of behaviour and intellectual function. Detailed studies would, however, require knowledge of the transmitter used by the perforant path fibres. Quite apart from the problem of synaptic plasticity, identification of the perforant path transmitter would add substantially to our knowledge of excitatory transmitters in the central nervous system. Here we present pre- and postsynaptic evidence that these fibres use glutamate as their transmitter.

We have previously shown that endogenous glutamate is released by dentate slices<sup>7</sup> and hippocampal synaptosomes<sup>8</sup> in a manner characteristic of transmitter substances and that this release originates in part from the perforant path fibres<sup>9</sup>. These fibres do not release aspartate<sup>9</sup> or  $\gamma$ -aminobutyrate (GABA)<sup>10</sup>. There was also a suggestion<sup>9</sup>, since confirmed<sup>11</sup>, that the perforant path boutons transport glutamate by a high affinity process. While these observations show that glutamate may be the transmitter at the perforant path-granule cell synapse, one could object that the slices and synaptosomes were depolarised only by chemical, and therefore non-physiological, stimuli and that no evidence has been presented implicating glutamate in the postsynaptic response. We have now shown that electrical field stimulation releases endogenous glutamate from slices of the fascia dentata and that a glutamate antagonist reduces the efficacy of perforant path stimulation.

In eight experiments a longitudinal slice of the internal leaf of the rabbit fascia dentata was electrically stimulated while being continuously superfused. When the slice was superfused with a physiological medium containing 2 mM free  $\text{Ca}^{2+}$ , electrical stimulation elevated the rate of glutamate release by a maximum of 300–1,200 pmol per 30 s per mg protein. In three experiments one slice was superfused with normal medium and another with  $\text{Ca}^{2+}$ -free medium supplemented with  $\text{Mg}^{2+}$  and  $\text{Mn}^{2+}$  to avoid membrane destabilisation (Fig. 1). Superfusion with a  $\text{Ca}^{2+}$ -free medium reduced glutamate output in response to stimulation by 62, 78 and 90%. Thus electrical stimulation, like elevated  $\text{K}^+$  and veratridine<sup>7</sup>,

**Fig. 1** Time course of glutamate efflux from a slice of fascia dentata in the presence and absence of  $\text{Ca}^{2+}$ . In each experiment a single 0.35-mm thick longitudinal slice of the free edge (internal leaf) of the fascia dentata was cut from a dissected rabbit hippocampus and immersed in a physiological medium at 37 °C for 5–10 min. Then the slice was superfused with the same 37 °C-medium at 1 ml min<sup>-1</sup> in a 0.5-ml chamber equipped with spiral silver electrodes. During the period indicated by the dotted bar the tissue was stimulated at 100 Hz with 10 V square wave pulses of alternating polarity and 5 ms duration. Superfusate fractions were collected continuously, and their glutamate content was determined by a micro-enzymatic fluorometric method<sup>18</sup>. The figure shows results from one set of paired experiments. Solid lines, glutamate efflux into normal medium (2 mM free  $\text{Ca}^{2+}$ ); dashed lines, glutamate efflux into  $\text{Ca}^{2+}$  free medium (with 25 mM  $\text{MgCl}_2$  and 0.1 mM  $\text{MnCl}_2$ ).

releases glutamate from the fascia dentata in a  $\text{Ca}^{2+}$ -dependent manner. Since extracellular  $\text{Ca}^{2+}$  is required for transmitter release<sup>12</sup>, but not for carrier-mediated efflux<sup>13</sup>, this finding agrees with previous evidence<sup>8</sup> that the glutamate released from fascia dentata by depolarising stimuli originates mainly from presynaptic transmitter stores.

The question remains as to whether the glutamate presumably released by stimulation of the perforant path fibres produces the excitatory postsynaptic potential (e.p.p.) recorded in the granule cell. Proof of this hypothesis requires the demonstration that glutamate and the perforant path transmitter exert physiologically and pharmacologically identical actions on the granule cell. As a first approach to this problem, we have examined the effect of the glutamate analogue, DL-2-amino-4-phosphonobutyric acid (APB), on perforant path responses in the hippocampal slice preparation<sup>6,14</sup>. APB competitively

**Table 1** Effect of APB on averaged responses to perforant path stimulation

	Amplitude of extracellular negativity (% of control)				Recovery			
	1	3	5	10 min	1	3	5	10 min
Drug (7)	61 ± 5	51 ± 3	48 ± 4	42 ± 4	56 ± 6	68 ± 6	68 ± 8	74 ± 9
No drug (5)	97 ± 2	94 ± 3	89 ± 4	82 ± 6	82 ± 7	77 ± 7	79 ± 9	76 ± 11

Responses of granule cell populations to perforant path stimulation were recorded as shown in Fig. 2. Amplitudes of these extracellularly recorded potentials were averaged over a period of 50 s at the times indicated. Values are expressed as mean percentages of the averaged potentials recorded within the 50-s period immediately preceding the introduction of APB into the medium ( $\pm$ s.e.m. for the number of slices in parentheses). In experiments without APB response amplitudes were averaged at comparable times after the beginning of stimulation.

and reversibly antagonises the action of glutamate iontophoretically applied to invertebrate muscle fibres<sup>15</sup> and in millimolar concentrations inhibits neuromuscular transmission<sup>16</sup>. Since invertebrate motoneurons almost certainly use glutamate as their transmitter<sup>17</sup>, APB seems to inhibit synaptic transmission mediated by glutamate. Accordingly, we stimulated the perforant path fibres in the presence and absence of 2.5 mM APB and recorded the extracellular field potentials in the molecular layer of the fascia dentata.

The results of one such experiment are shown in Fig. 2. When the perforant path fibres were continuously stimulated at 0.2 Hz, a sizeable negative potential was recorded whose amplitude declined to some extent over a 22-min period (Fig. 2a), probably as a result of habituation<sup>2,3</sup>. Introduction of APB into the superfusion medium substantially reduced the amplitude of the potential within 1 min (Fig. 2b). The amplitude recovered just as rapidly upon return to normal medium and finally reached the habituated level.

Table 1 summarises the variation of averaged extracellularly recorded potential amplitudes with time in the presence or absence of APB. By comparison with responses in normal medium averaged at similar times after the onset of stimulation, APB was seen to have been maximally effective within 3 min (46% reduction), and 3 min of washout was sufficient to terminate

**Fig. 2** Reduction of perforant path responses by APB. Slices of 0.7-mm thickness were cut transverse to the long axis of dissected hippocampi, and each was placed on a fritted polypropylene disk within a superfusion chamber. Electrodes were lowered into the chamber, and then the slice was superfused at a rate of 2.5 ml min<sup>-1</sup> with Elliott's medium<sup>19</sup> warmed to 32 °C. When the slices showed synaptic activity (1–2 h later), a bipolar stimulating electrode was inserted into the perforant path where it passes through the subiculum and a micropipette recording electrode (3–12 MΩ) into the perforant path terminal zone. The perforant path fibres were stimulated continuously with square wave pulses of 0.05 ms duration at 0.2 Hz and an intensity just below that which evoked a population spike. *a*, Amplitude of every second extracellularly recorded synaptic potential (dots) in a single experiment without drug; *b*, results of an experiment in which 2.5 mM APB was present in the medium during the period denoted by the open bar. Examples of recorded potentials are shown at the times they were evoked.

the effect of the drug. This result indicates, as expected, a readily reversible antagonism.

To determine whether APB exerted merely a local anaesthetic action, we determined its effect on the antidromic potential elicited by stimulation of the mossy fibres (granule cell axons). In four experiments APB did not alter the amplitude or form of the extracellularly recorded potentials, thus ruling out the possibility that APB acted by reducing the excitability of the granule cells. Also in several experiments APB was seen not to affect presynaptic fibre potentials.

APB probably did not act on the presynaptic boutons, since at 2.5 mM it did not reduce the quantity of glutamate released by elevated K<sup>+</sup> or affect the high affinity transport of glutamate. It, therefore, seems to exert its effect at the postsynaptic level, suggesting a pharmacological identity between glutamate and the perforant path transmitter. This conclusion must be tentative, however, until it can be rigorously shown that APB acts as a glutamate antagonist at this particular synapse.

The results of this and previous studies suggest that perforant path boutons release glutamate from a transmitter store and that the glutamate so released might then depolarise the granule cell. Thus, glutamate is most likely the transmitter used at the perforant path-granule cell synapse. Our results with APB, moreover, suggest that this antagonist will prove a useful tool in dissecting the mechanisms which underlie synaptic plasticity at this site.

## Regulation of prolactin release by endogenous opiates

ENDORPHINS, the endogenous peptides recently isolated and identified in brain have been implicated in regulation of pain<sup>1–4</sup>. But their wide distribution throughout the brain<sup>5–7</sup> and their profound behavioural effects after central administration<sup>8</sup> suggest an involvement in other central nervous system processes. Immunohistochemical identification of

these endorphins (refs 9, 10 and F. Bloom, personal communication) in hypothalamic neurones indicated that neuroendocrine effects are probable. Morphine was previously reported to block ovulation, while more recently, morphine<sup>11</sup> and endorphins<sup>12-14</sup> were observed to stimulate release of prolactin and growth hormone. Yet, these observations have not established a direct, tonic participation of endorphins in hypothalamic and anterior pituitary function. The absence of any direct action of opiate antagonists has been taken as an argument against any tonic role of endorphins. Recent reports indicate, however, that opiate antagonists do modify on-going central processes. For example, naloxone and naltrexone lower pain threshold in appropriate conditions in man and experimental animals<sup>15-18</sup>. Using naltrexone as a tool to block opiate receptor function, we have explored whether endorphins are tonically involved as a putative neurotransmitter in the regulation of prolactin release. The results presented here demonstrate a new instance where an opiate antagonist modifies normal function. The data agree with a preliminary report indicating that naloxone reduced prolactin release in immature female rats<sup>19</sup>.

As shown in Table 1, naltrexone at a dose of 1 mg per kg body weight produced a 50% decrease of serum prolactin concentration of male rats in 20 min. This decrease lasted for more than 2 h and was observed when blood was collected by decapitation or by cardiac puncture. The prolactin decrease elicited by naltrexone was the same in rats with a deafferented hypothalamus (Table 1), so we infer that the inhibition of prolactin release reflects a direct effect of naltrexone at the hypothalamic-pituitary level. Large amounts of  $\beta$ -endorphin are reported to be present in the pituitary<sup>20-22</sup>. We have examined whether naltrexone inhibits prolactin release from isolated pituitary gland *in vitro*. When pituitary halves were incubated without or

with naltrexone in concentrations up to  $10^{-4}$  M, the prolactin release was similar in the treated and untreated halves. The ability of naltrexone to reduce prolactin release stimulated by various mechanisms was also studied. The models used were: (1) chronically elevated prolactin release in oestrogen-primed ovariectomised rats; (2) prolactin release elicited by foot shock in male rats; (3) prolactin release elicited by intrahypothalamic injections of  $\beta$ -endorphin in intact rats or by systemic injection of morphine in deafferented rats; and (4), prolactin release elicited by a dopamine receptor blocker or monoamine depletor.

As shown in Table 1, naltrexone had different effects in these four models. In oestrogen-primed ovariectomised rats, naltrexone at 0.25 mg per kg intraperitoneally (i.p.) produced a significant (48%) inhibition of serum prolactin concentration. Doses of naltrexone of 1 or 5 mg per kg i.p. produced approximately a 60% decrease of hormone secretion. In addition, naltrexone is a very powerful inhibitor of the prolactin release occurring after foot shock (Table 1). It has been reported that intraventricular or systemic injection of  $\beta$ -endorphin or morphine stimulates the release of prolactin in rat<sup>12,23</sup>. To demonstrate that naltrexone acts in the hypothalamus to interfere with the opiate receptor agonist, we injected  $\beta$ -endorphin into the mediobasal hypothalamus (cannula placement was verified histologically) and naltrexone i.p. The release of prolactin induced by 1  $\mu$ g of  $\beta$ -endorphin can be blocked by 1 mg naltrexone per kg, i.p., injected 10 min previously (Fig. 1a). Similarly, the increase of serum prolactin induced by morphine in animals with a deafferented hypothalamus was blocked by naltrexone (Fig. 1b). In contrast, naltrexone failed to inhibit the prolactin release (see Table 1) elicited by haloperidol, a powerful inhibitor of dopamine receptors or by reserpine, a depletor of central monoamine stores.

These observations show that  $\beta$ -endorphin stimulates

Table 1 Effects of naltrexone on prolactin (PRL) release

Intact, Sprague-Dawley, male rats (180-250 g body weight), deafferented male rats 6-15 d after hypothalamic isolation<sup>24</sup> or ovariectomised female rats (30 d after surgery) primed with 5  $\mu$ g oestradiol benzoate for 5 d were used. Male rats given haloperidol (0.25 mg per kg, i.p.) or reserpine (2 mg per kg, i.p.) were used 45 min and 6 h later. Foot shock (1 mA, 1-s shock per 5 s) was administered for 10 min immediately before killing. Blood samples were collected by decapitation 20 min after i.p. naltrexone or 0.85% NaCl injection or in other cases, by cardiac puncture under light ether anaesthesia before and 20 min after naltrexone or vehicle injection. Serum was separated after overnight clotting at 4 °C. Prolactin was measured using the NIAMD rat prolactin radioimmunoassay kit provided by NIAMD-NIH Pituitary Hormone Program. Mean serum prolactin (PRL) concentration of naltrexone treated rats was compared to control rats and considered significantly different if  $P < 0.05$ . Treatment effects are described as  $\bar{x}$  serum prolactin concentration of naltrexone treated rats/ $\bar{x}$  serum prolactin concentration of controls  $\times 100$  when rats were decapitated. In experiments where pre- and post-treatment samples were collected, a post-treatment/pre-treatment % was calculated for each rat and mean percentages (post/pre-treatment  $\times 100$ ) were then calculated for each group. In this group statistical significance was evaluated according to the Student's paired *t* test. *n*, No. of animals per group. \* $P < 0.05$ .

**Fig. 1 a**, Male rats (150–180 g) were implanted with a guide cannula in the mediobasal hypothalamus (4 mm A–P, 0.5 L, 8.6 D–V; König and Klippel<sup>26</sup>) and injected 3–5 d later with endorphin or vehicle in a volume of 1  $\mu$ l in 2 min. Naltrexone (1 mg per kg, i.p.) or 0.85% NaCl was given 10 min before endorphin injection. Blood was collected by decapitation. Cannula position was verified histologically after decapitation. **b**, Male rats (250–300 g) were used 8–16 d after hypothalamic isolation<sup>25</sup>. Rats were given, systemically, naltrexone in 0.85% NaCl and morphine sulphate or 0.85% NaCl at 10 min and blood was collected by cardiac puncture under light ether anaesthesia. Completeness of deafferentation was determined from histological sections of the brain. PRL, prolactin;  $\alpha$ -END,  $\alpha$ -endorphin;  $\beta$ -END,  $\beta$ -endorphin; NTX, naltrexone; MOR, morphine.

prolactin release by activation of opiate receptors. More importantly, these experiments indicate that the release of prolactin in physiological conditions can be reduced by a blockade of opiate receptors and suggest that endogenous opiate receptor ligands participate tonically in the regulation of anterior pituitary hormone secretion during basal conditions or when release is stimulated by oestrogen or by excitation of the hypothalamus as during stress.

In agreement with histoimmunological localisation of endorphins (refs 9, 10, and F. Bloom, personal communication) the action of these peptides can be located in the mediobasal hypothalamus. Naltrexone fails to inhibit the prolactin release from the pituitary but it is effective when the mediobasal hypothalamus is attached to the pituitary. It seems that the arcuate nucleus median eminence dopaminergic tract may be involved in the action of opiates since its inactivation pharmacologically prevents the action of naltrexone on prolactin release. Indeed, Ferland *et al.*<sup>24</sup> have shown that enkephalin may affect these dopaminergic neurones. It is possible that endorphins and dopamine regulate prolactin release according to an arrangement in which the two neurones act in series. Although further studies are needed to establish the precise role of hypothalamic endorphins in the regulation of prolactin release, these experiments provide strong evidence suggesting their participation.

## Immunoreactive component resembling cholecystokinin octapeptide in intestine

MANY hormones exist in several molecular forms. The intestinal hormone cholecystokinin has been isolated from hog duodenum in the form of peptides of 33 and 39 amino acid residues (CCK33 and CCK39)<sup>1–4</sup>. Extracts of hog cerebral cortex have been shown to contain components with CCK-like immunoreactivity<sup>5</sup>, but on gel filtration the main component in brain had the properties of the COOH-terminal octapeptide (CCK8) of CCK33 and CCK39<sup>6</sup>. Several other hormonal and related peptides probably occur in identical forms in brain and gut<sup>6</sup>, so it seemed possible that a CCK8-like factor would also be found in intestine. Synthetic CCK8 is known to be about twice as potent on a molar basis as CCK33 on the main target organs of the hormone (gall bladder and exocrine pancreas)<sup>7</sup> so that the possible existence of CCK8 in the intestine is of physiological significance. We have studied immunoreactive CCK-like factors in extracts of hog duodenum and jejunum and we report here the presence of relatively high concentrations of a CCK8-like component. This factor was poorly extracted by the method used to purify CCK33 and CCK39 which may explain why it was previously overlooked.

Mutt and Jorpes obtained CCK33 and CCK39 from hog intestine by first immersing the tissues in boiling water to inactivate proteases, and then transferring them to acetic acid for extraction<sup>1,2</sup>. Basic peptides in the extract, including CCK33 and CCK39, were adsorbed on alginic acid and eluted with HCl. In the present study pieces of hog duodenum, jejunum, antral mucosa and cerebral cortex were extracted either in boiling water or in boiling 0.5 M acetic acid. The tissues (0.5 g ml<sup>-1</sup>) were briefly boiled (2–3 min), homogenised and centrifuged (2,000g, 10 min). When acid extracts of duodenum or jejunum were fractionated on Sephadex G-50 the main peak of immunoreactivity in the column eluates detected by radioimmunoassay using an antiserum which cross-reacts with CCK8 and CCK33, emerged in the position of CCK33 (Fig. 1, component II<sup>B</sup>). This component could be adsorbed on alginic acid and eluted with HCl and is therefore compatible with CCK33 obtained by Mutt and Jorpes. On gel filtration, boiling water extracts of intestine contained little or no activity resembling CCK33 but did contain two other major peaks of immunoreactivity (Fig. 1, components III and IV), which would presumably be discarded in the first step of the Mutt and Jorpes method. The larger of the two peaks (IV) eluted in the region of CCK8 and the other emerged between calibration standards of CCK8 and CCK33 and is therefore probably of intermediate size. Both factors could be ad-

**Fig. 1** Elution profiles of boiling water (neutral) and boiling 0.5 M acetic acid extracts of hog jejunum and cerebral cortex on Sephadex G-50 (1 × 100 cm). In each case the equivalent of 0.5 g tissue was applied to the column. Immunoreactivity in the column eluates was estimated by radioimmunoassay using an antiserum (C) raised against CCK8 and <sup>125</sup>I-labelled CCK8; with this antiserum the ratio of immunoreactivity CCK8:CCK33, was 1.0:0.60 on a molar basis; immunoreactivity in column eluates is expressed in terms of standard CCK8. Elution volumes are expressed as % from protein peak (0%) estimated by absorption of 280 nm, to <sup>125</sup>I (100%) added as a marker to all samples. In separate runs the columns were calibrated with pure natural human big gastrin (G34), little gastrin (G17), pure natural porcine CCK33 and CCK39, synthetic caerulein (Caer) and CCK8. Elution volumes of these standards are indicated by arrows; CCK 39 emerges in the same position as CCK 33. a, Intestine neutral extract; b, intestine acid extract; c, brain neutral extract; d, brain acid extract.

**Table 1** Concentration (pmol ml<sup>-1</sup>) of intestinal peaks III and IV in samples pooled from Sephadex G-50 eluates and estimated by four COOH-terminal specific antisera and pure human G17 or CCK8 standards

	Standard	Antiserum			
		C	2716	1296	L2
Component III	G17	60.00	7.60	2.90	0.70
	CCK8	18.30	47.00	30.00	63.00
Component IV	G17	9.80	0.80	0.40	0.05
	CCK8	3.20	2.60	3.20	4.40

Antiserum C was used with <sup>125</sup>I-labelled CCK8 when CCK8 was the standard, and with <sup>125</sup>I-labelled G17 when G17 was the standard. The other antisera were raised against G17 and used with <sup>125</sup>I-labelled G17 for both G17 and CCK8 standards. Dilution curves of the brain extracts were parallel to the standard curve in each case.

sorbed on DEAE and eluted with ammonium carbonate suggesting that they are acidic peptides. Minor components (I and II<sup>A</sup>) were present in both acid and boiling water extracts (Fig. 1). Intestinal components I and IV emerged in the same position as factors previously identified in brain extracts<sup>3</sup>. Immunoreactivity corresponding to intestinal components II and III was present in negligible amounts in brain, however (Fig. 1). The failure to find significant quantities of a CCK33-like component in brain is not likely to be due to degradation during extraction for standard CCK33 was recovered in good yield (> 80%) when added to acid extracts of brain. Similarly the different patterns of components in acid and boiling water extracts of intestine are not likely to arise from interconversion during extraction, because when the residue of boiling water extracts was re-extracted with 0.5 M acetic acid CCK33-like activity was obtained in good yield (> 80%) compared to direct acid extraction.

Gastrin and CCK share the same COOH-terminal pentapeptide and antisera specific for the COOH-terminus of one hormone frequently cross-react with the other. But, immunochemical studies with antisera of different specificity support the suggestion that intestinal components III and IV are COOH-terminal fragments of CCK. Gastrin antisera (1295 and L6) which do not cross-react with CCK<sup>8,9</sup>, revealed negligible amounts of immunoreactive material in extracts of duodenum, jejunum or brain (< 0.5 pmol g<sup>-1</sup>), but high concentrations in antral mucosa (> 2 nmol g<sup>-1</sup>). Furthermore, in radioimmunoassays using four COOH-terminal specific antisera which cross-react to different degrees with heptadecapeptide gastrin (G17) and CCK8, there were only minor differences between antisera (two- to fourfold) in estimating concentrations of components III and IV when referred to a standard of CCK8 (Table 1). In contrast, when G17 was used as a standard there were up to 200-fold differences in estimates made with different antisera. Similar results have been obtained using a variety of COOH-terminal fragments of gastrin and CCK as standards; together the data indicate that with this panel of antisera the pattern of cross-reactivity of the intestinal components is readily distinguishable from gastrin-like but not CCK-like peptides.

Intestinal components II and III could also be distinguished from G17 and smaller gastrin-like peptides because they were converted by trypsin to a component emerging just before CCK8 (90% elution volume) on Sephadex G-50 whereas G17 and small fragments are resistant to trypsin. A similar tryptic peptide was obtained by trypsinisation of pure CCK33, and probably corresponds to the COOH-terminal dodecapeptide previously identified as a product of mild trypsinisation of CCK33<sup>3,3</sup>. Intestinal component IV, like CCK8, was resistant to trypsin.

Estimation of the absolute concentration of the different intestinal components must await their purification and

characterisation. But, in radioimmunoassays using antisera raised against CCK8, and the appropriate standard (CCK8 or CCK33), it was estimated from immunoreactivity in column eluates that concentrations of the CCK8-like factor in duodenum ( $40 \text{ pmol g}^{-1}$ ) were about twice those of CCK33 ( $19 \text{ pmol g}^{-1}$ ). In jejunum, on the other hand, concentrations of the CCK8-like factor ( $15 \text{ pmol g}^{-1}$ ) were about half those of CCK33 ( $27 \text{ pmol g}^{-1}$ ). Using CCK8 standard the concentration of component III was estimated to be  $20 \text{ pmol g}^{-1}$  in duodenum and  $10 \text{ pmol g}^{-1}$  in jejunum. Because COOH-terminal fragments of CCK larger than the heptapeptide have strong CCK-like actions<sup>7</sup>, the intestinal CCK8-like factor could make an important, possibly even the major, contribution to the biological activity of cholecystokinin released from the duodenum.

Several interesting questions are posed by the different patterns of distribution of CCK-like peptides in brain and gut. It is now recognised that many polypeptide hormones are synthesised via large precursor molecules which are converted to smaller active molecules by proteolytic cleavage<sup>10</sup>. Thus the different forms of CCK could be derived from precursor which was cleaved at different positions in brain and intestine. Even within the small bowel there may be differences in the patterns of biosynthetic processing of CCK, for there were differences in the relative amounts of CCK8- and CCK33-like activity in the duodenum and jejunum. For many hormones, for example, insulin and parathyroid hormone, the site at which the prohormone is cleaved to yield the active hormonal peptide consists of two or more consecutive basic amino acid residues, and is susceptible to digestion by trypsin-like enzymes<sup>10</sup>. Only a single basic residue (arginine) links CCK8 to the NH<sub>2</sub>-terminal portion of CCK33, however, and this position is relatively resistant to trypsin. If, as seems likely, CCK33 is a prohormone for CCK8 then conversion is probably mediated by a specific enzyme.

We thank Elaine Clarke, Carol Higgins and Gavin Laing for technical assistance, Drs S. Bloom and J. Rehfeld for antisera ('C' and 2716 respectively), Professor R. A. Gregory and Dr H. J. Tracy for pure human G17 and G34, Professor V. Mutt for pure porcine CCK33 and CCK39 and the Squibb Institute of Medical Research for CCK8. The work was supported by a grant from the MRC.

## Specific binding of <sup>3</sup>H-mepyramine to histamine H<sub>1</sub> receptors in intestinal smooth muscle

THE specific binding of high-affinity ligands to a wide range of pharmacological receptors has been used to obtain information on receptor numbers, distribution and the characteristics of agonist and antagonist binding. The first study of this type, by Paton and Rang<sup>1</sup>, was of the binding of <sup>3</sup>H-atropine to muscarinic receptors in guinea pig intestinal smooth muscle. The histamine H<sub>1</sub> receptor has not previously been studied,

and here we describe the specific binding of mepyramine, an H<sub>1</sub>-selective antagonist<sup>2</sup>, to histamine H<sub>1</sub> receptors in homogenates of the longitudinal muscle-myenteric plexus preparation from guinea pig small intestine.

<sup>3</sup>H-Mepyramine was synthesised by catalytic hydrogenation with tritium gas of the 5-bromopyridyl derivative. The method will be described in detail elsewhere. The purity of the product was established by the identity with authentic non-radioactive mepyramine of (1) the *R<sub>F</sub>* value on thin-layer chromatography in three solvent systems, (2) the mobilities on high-voltage electrophoresis and (3) the ultraviolet spectrum. The affinity constant of <sup>3</sup>H-mepyramine for the histamine H<sub>1</sub> receptor,  $1.6 \pm 0.4 \times 10^9 \text{ M}^{-1}$  (three measurements), deduced from the parallel shift of the log dose-response (contraction) curve of longitudinal muscle strips to histamine, was not significantly different from that of non-radioactive mepyramine,  $1.2 \pm 0.3 \times 10^9 \text{ M}^{-1}$  (six measurements), the figures being in accord with values in the literature<sup>2-4</sup>. The concentration of <sup>3</sup>H-mepyramine was determined from the absorbance at 310 nm. The specific activity of the purified product was  $20 \text{ Ci mmol}^{-1}$ .

The binding of <sup>3</sup>H-mepyramine, either alone or in the presence of  $2 \times 10^{-6} \text{ M}$  non-radioactive mepyramine, to homogenates of longitudinal muscle strips from guinea pig small intestine and the difference curve, which is taken to represent the receptor-specific binding, is shown for a representative experiment in Fig. 1. The difference between all pairs of points was statistically significant ( $P < 0.05$ ). The best-fit<sup>5</sup> parameters for the experiment in Fig. 1, assuming binding follows simple mass-action kinetics, were  $1.7 \pm 1.0 \text{ nM}$  for *K<sub>d</sub>*, the dissociation

**Fig. 1** *a*, Binding of <sup>3</sup>H-mepyramine to homogenates of guinea pig intestinal smooth muscle. Longitudinal muscle strips from guinea pig small intestine, prepared essentially as described by Rang<sup>10</sup>, were chopped with scissors, partially homogenised in five volumes of 50 mM sodium-potassium phosphate buffer, pH 7.5, in a glass homogeniser with a glass pestle and the ice-cold suspension then treated twice with a Polytron blender (setting 5 for 15 s). Homogenate (0.2 ml, approximately 2 mg protein) in 1.8 ml 50 mM sodium-potassium phosphate buffer, pH 7.5, was incubated with various concentrations of <sup>3</sup>H-mepyramine in the presence (○) or absence (●) of  $2 \times 10^{-6} \text{ M}$  mepyramine for 60 min at 30 °C. Aliquots (0.25 ml) were centrifuged at 8,700g for 60 s in a Beckman Microfuge B and the pellet washed superficially twice with 0.1 ml ice-cold phosphate buffer. The tritium in the pellet was determined by liquid scintillation counting. Values are means  $\pm$  s.e. of quadruplicate determination of two to four incubations. *b*, Receptor-specific binding; obtained by subtracting the binding of <sup>3</sup>H-mepyramine in the presence of  $2 \times 10^{-6} \text{ M}$  mepyramine from the uninhibited binding. The curve is a best-fit curve calculated by the method of Wilkinson<sup>5</sup>.

constant and  $77 \pm 15$  pmol per g protein for the number of binding sites. The best-fit values obtained by combining data from a number of such experiments were  $1.3 \pm 0.3$  nM and  $68 \pm 7$  pmol per g protein, although the maximum amount of  $^3\text{H}$ -mepyramine binding seemed to vary between homogenates (compare Table 2). The affinity constant,  $7.7 \pm 1.8 \times 10^8 \text{ M}^{-1}$  ( $1/K_d$ ) is in reasonable agreement with the value,  $1.6 \pm 0.4 \times 10^9 \text{ M}^{-1}$ , obtained from inhibition of the contractile response.

To establish that the binding of  $^3\text{H}$ -mepyramine sensitive to inhibition by  $2 \times 10^{-6} \text{ M}$  mepyramine does represent receptor-specific binding we have examined the inhibition of  $^3\text{H}$ -mepyramine binding by three compounds considered to be selective antagonists at histamine  $\text{H}_1$  receptors, chlorpheniramine, promethazine and triprolidine, and by two drugs having their primary effect on other receptors, burimamide (histamine  $\text{H}_2$ ) and lachesine (muscarinic). The maximal inhibition of  $^3\text{H}$ -mepyramine binding by each drug did not differ significantly from that produced, measured on the same homogenate, by  $2 \times 10^{-6} \text{ M}$  mepyramine. The curves for the inhibition by the  $\text{H}_1$  antagonists of the receptor-specific binding approximated to hyperbolae and the affinity constants (Table 1) calculated from values for 50% inhibition compared well with those in the literature obtained from inhibition of the contractile response. The two non- $\text{H}_1$  antagonists were only weak inhibitors of  $^3\text{H}$ -mepyramine binding. The affinity constant deduced for lachesine,  $1.6 \times 10^5 \text{ M}^{-1}$ , is in good agreement with the value<sup>6</sup> from antagonism of the response to histamine,  $1.0 \times 10^5 \text{ M}^{-1}$ ,

Table 1 Inhibition of  $^3\text{H}$ -mepyramine binding

Drug	Affinity constant ( $\text{M}^{-1}$ ) from inhibition of		(ref.)
	$^3\text{H}$ -mepyramine binding*	Contraction†	
Mepyramine	$1.0 \times 10^9$	$1.2 \times 10^9$	
(±) Chlorpheniramine	$7.6 \times 10^8$	$6.6 \times 10^8$	(3)
Promethazine	$4.4 \times 10^8$	$8.5 \times 10^8$	(3)
Triprolidine	$1.0 \times 10^9$	c. $10^9$	(9)
Burimamide	c. $10^4$	$3.5 \times 10^3$	(8)
Lachesine	$1.6 \times 10^5$	$1.0 \times 10^5$	(6)

\* Incubations as in Fig. 1 with  $10^{-9} \text{ M}$   $^3\text{H}$ -mepyramine. The affinity constants,  $K_a$ , of the inhibitors were calculated from the relationship  $K_a = (K_{\text{mep}} [M] + 1)/[A]$ , where  $[A]$  is the concentration of drug required for 50% inhibition of receptor-specific  $^3\text{H}$ -mepyramine binding,  $[M]$  is the concentration of  $^3\text{H}$ -mepyramine and  $K_{\text{mep}}$  its affinity.  $K_{\text{mep}}$  was taken to be  $1.2 \times 10^9 \text{ M}^{-1}$ , the mean of the various determinations made.

† From inhibition of the contractile response to histamine of intact segments or longitudinal muscle strips from guinea pig ileum. In our own measurements  $K_a$  was obtained from the relationship for competitive inhibition: dose ratio  $- 1 = [A] \times K_a$ , where the dose ratio is the ratio of the dose of agonist necessary to achieve a given response in the presence of antagonist, concentration  $[A]$ , to the dose required with no antagonist present.

a figure four orders of magnitude lower than its affinity for the muscarinic receptor<sup>7</sup>,  $1.1 \times 10^9 \text{ M}^{-1}$ . The affinity of burimamide as an inhibitor of  $^3\text{H}$ -mepyramine binding, about  $10^4 \text{ M}^{-1}$ , is an order of magnitude less than its affinity at the  $\text{H}_2$  receptor<sup>8</sup>,  $1.3 \times 10^5 \text{ M}^{-1}$ .

The number of histamine  $\text{H}_1$  receptors in homogenates of guinea pig intestinal smooth muscle, 68 pmol per g protein, is apparently much smaller than the number of muscarinic receptors reported in this tissue<sup>11-13</sup>, but the criterion per g protein clearly makes the number obtained very dependent on the degree of purification of the membrane fraction and the assay technique employed. To make a more direct comparison between the numbers of histamine  $\text{H}_1$  and muscarinic receptors, in five experiments the maximum receptor-specific binding of  $^3\text{H}$ -mepyramine was compared on the same homogenate with that of  $^3\text{H}$ -quinuclidinyl benzilate ( $^3\text{H}$ -QNB), a muscarinic ligand<sup>14</sup>. The relative amounts of the two receptors varied within a fairly narrow range (Table 2) giving a mean value of

Table 2 Comparison of the numbers of histamine  $\text{H}_1$  and muscarinic receptors in guinea pig intestinal smooth muscle

Expt	No. of receptors (pmol per g protein)		$\text{H}_1/\text{Muscarinic} (\%)$
	Histamine $\text{H}_1$	Muscarinic	
1	82*	496	17
2	41*	407*	10
3	62*	297	21
4	93	493	19
5	45	334	13
Mean	$65 \pm 10$	$405 \pm 41$	$16 \pm 2$

The no. of receptors was estimated either (\*) from the maximum specific binding obtained from binding curves in the presence and absence of  $2 \times 10^{-6} \text{ M}$  mepyramine (for  $^3\text{H}$ -mepyramine; see Fig 1) or  $2 \times 10^{-6} \text{ M}$  methylatropinium bromide (for  $^3\text{H}$ -QNB) or (values not starred) from the receptor-specific binding with  $7.5 \times 10^{-9} \text{ M}$   $^3\text{H}$ -mepyramine or  $7.7 \times 10^{-9} \text{ M}$   $^3\text{H}$ -QNB. In each experiment measurement of the numbers of the two receptors was made on the same homogenate.  $^3\text{H}$ -QNB ( $^3\text{H}$ -quinuclidinyl benzilate), specific activity  $13 \text{ Ci mmol}^{-1}$ , was obtained from the Radiochemical Centre, Amersham.

$16 \pm 2$  for the number of  $\text{H}_1$  receptors as a percentage of the number of muscarinic receptors. This figure must still, however, be viewed with some caution. The composition of the assay medium, 50 mM sodium potassium phosphate, does not correspond to the *in vivo* environment and while the number of muscarinic receptors determined by antagonist binding seems to be insensitive to the ionic composition<sup>15</sup> it remains to be established whether this also holds for mepyramine.

As far as we are aware this is the first report of binding studies on the histamine  $\text{H}_1$  receptor using a selective high-affinity antagonist. There has been a report<sup>16</sup> that by using suitable protecting agents the histamine receptor in cat intestinal muscle could be labelled with the relatively nonspecific antagonist  $^3\text{H}$ -dibenamine ( $58.5 \text{ mCi mmol}^{-1}$ ). The amount of presumed receptor material labelled seems remarkably large, however, being some 200-fold greater than that bound by  $^3\text{H}$ -mepyramine in our experiments and indeed an order of magnitude greater than the highest reported estimate of the number of muscarinic receptors in intestinal smooth muscle. Even allowing for species differences there must be some suspicion that the bulk of the dibenamine was bound to non-receptor sites.

These observations suggest that  $^3\text{H}$ -mepyramine should be a valuable tool with which to investigate the numbers of histamine receptors in various tissues in various conditions and to study the binding characteristics of  $\text{H}_1$  agonists and antagonists.

## Presumptive control mutation for alcohol dehydrogenase in *Drosophila melanogaster*

EXAMPLES of control mutations are rare in eukaryotes. Indeed, the only well-documented examples are in *Aspergillus*<sup>1,2</sup> and a mutant affecting xanthine dehydrogenase (XDH) activity and mapping adjacent to, but separable from, *rosy*, the structural gene for XDH in *Drosophila melanogaster*<sup>3,4</sup>. Control of alcohol dehydrogenase (ADH), particularly in *Drosophila* has recently been studied. In examining ADH activity in selection lines and in samples from natural populations, a line was found to be *Adh*<sup>S</sup> and to have half the activity of a normal slow-migrating allele. To test the hypothesis that the low activity *Adh*<sup>S</sup> line contains a control mutation, we have attempted to separate the activity phenotype from the electrophoretic (structural gene) phenotype by recombination. We have succeeded in doing this, and in the process have obtained a very accurate position for *Adh* based on its recombination with closely-linked marker loci.

ADH is a small homodimer with a molecular weight of about 24,000 (R. Ambler, personal communication). The alcohol dehydrogenase (*Adh*) locus maps at position 50.1 on the second chromosome of *D. melanogaster*, and its cytogenetic location is known within two bands (35B2–3) on the polytene chromosome map of salivary glands<sup>5</sup>.

In addition, *Adh* is highly polymorphic in nature<sup>6–8</sup>. Activity variation is also known<sup>9–11</sup> and we have identified a striking variant in a population collected near Cambridge, UK. A line derived from that population is homozygous for the slow-migrating allele (*Adh*<sup>S</sup>) but has only about half the activity of a standard *Adh*<sup>S</sup> allele, as measured by the rate at which it acts on the substrate isopropanol. Taking *Adh*<sup>F</sup> as a standard with relative activity of 1.0, we found the ratio of activities of *Adh*<sup>F</sup> to *Adh*<sup>S</sup> to 'low activity *Adh*<sup>S</sup>' to be approximately 1.0 : 0.57 : 0.28 (ref. 12). Radial immunodiffusion assays<sup>12</sup> have confirmed that the decreased activity is due to the fact that the allele produces about half as many enzyme molecules as the normal *Adh*<sup>S</sup> or *Adh*<sup>F</sup> alleles. Thus, it is a good candidate for a control mutation, though, as is the case for some mutations of XDH, this variant could affect the quantity of ADH by changing the primary sequence of the protein, and only protein chemistry can unambiguously rule out this possibility.

Let us represent the low activity allele as *Adh*<sup>S-L</sup>, the normal slow-mobility allele as *Adh*<sup>S-H</sup>, and the possible fast-mobility alleles as *Adh*<sup>F-L</sup> and *Adh*<sup>F-H</sup>, respectively. A multiply-marked second chromosome stock carrying *black* (*b*, 2–48.5), *elbow* (*el*, 2–50.0), *reduced-scraggly* (*rd*<sup>S</sup>, 2–51.2), *purple* (*pr*, 54.5), and *cinnabar* (*cn*, 2–57.5) was crossed to the *Adh*<sup>S-L</sup> stock, which is marked with the third chromosome mutation *veinlet*. The *Adh* locus maps between *el* and *rd*<sup>S</sup><sup>13</sup> and the *b el rd*<sup>S</sup> *pr cn* stock is homozygous for *Adh*<sup>F-H</sup>. Heterozygous females were backcrossed to *b el rd*<sup>S</sup> *pr cn* males and the progeny were scored for two recombinant classes: *b el* + + + and + + *rd*<sup>S</sup> *pr cn*. All other progeny were pooled and counted as non-recombinants for that region.

A total of 122 *b el* + + + and 128 + + *rd*<sup>S</sup> *pr cn* recombinant progeny were recovered among 59,738 scored. This allows us to calculate very accurately the map distance between the two morphological markers flanking the *Adh* locus. This distance is estimated to be 0.42 cM, much smaller than the estimate of 1.2 cM normally quoted<sup>13</sup>. Having such close flanking markers makes the recombinational assay of potential control mutants exceptionally accurate and efficient. Indeed, independent evidence suggests that there may be only one gene between *el* and *Adh*<sup>S</sup>.

Each + + *rd*<sup>S</sup> *pr cn* recombinant male was then mated to females heterozygous for *Df*(2L)64j (ref. 9), which includes the *el* and *Adh* loci, and for the balancer chromosome *Curly of Oster*. Homozygous + + *rd*<sup>S</sup> *pr cn* recombinant chromosomes were produced by standard crosses. A total of 35 of the 70 such chromosomes from males were successfully made homozygous. These were then tested for both ADH electrophoretic mobility and for enzyme activity.

Fig. 1 Order and estimated map distances for *Adh*, the low activity site (L) and flanking markers.

A total of 30 recombinants were *Adh*<sup>S</sup>. On the basis of the earlier estimate of the map distance between *el* and *rd*<sup>S</sup>, this places the *Adh* locus very near *el*, and about 0.36 cM from *rd*<sup>S</sup> (Fig. 1). Of greater importance, however, was the observation that one of the 30 *Adh*<sup>S</sup> lines had normal enzyme activity, while the other 29 still had low activity. The complementary *Adh*<sup>F-L</sup> recombinant has not yet been recovered. Thus, an activity modifier locus has been identified that is separable from, and to the right of, the *Adh* structural gene as marked by electrophoretic mobility alleles.

Other recombinants are now being studied. But the data so far have enabled us to measure accurately the recombination distance between two loci flanking the *Adh* locus and have provided the first evidence that a *presumptive* control mutation decreasing the number of enzyme molecules is located proximal, but very close, to the structural gene for alcohol dehydrogenase.

This work was supported in part by an MRC grant (G973/691/B) to M.A. and Professor B. Clarke.

## Synthesis of infectious $\Phi$ X-174 bacteriophage *in vitro*

STUDY of virus assembly has indicated the involvement of a diverse spectrum of protein-protein and protein-nucleic acid interactions (for review see ref. 1). In *Escherichia coli* cells infected with bacteriophage  $\Phi$ X-174, synthesis of single-stranded circular viral DNA requires the functions of at least seven phage-coded genes which include genes specifying viral structural proteins F, G and H non-virion proteins A, B, C and D. The only known phage gene that is not involved in single-stranded DNA synthesis is gene E (lysis) (for review see ref. 2). It seems that synthesis of single-stranded circular viral DNA of  $\Phi$ X-174 is very tightly coupled with the phage morphogenetic pathway. The synthesis of  $\Phi$ X-174 viral DNA involves a replicative form (RF) DNA with an extended tail of single-stranded viral DNA up to one genome in length ('rolling circle' or  $\sigma$  structure DNA)<sup>3-7</sup>. Fujisawa and Hayashi<sup>8,9</sup> found that  $\sigma$  DNA in infected cells is associated with a number of phage and host proteins as a 50S complex which is a precursor of mature phage particles. They have proposed that synthesis and packaging of  $\Phi$ X-174 single-stranded DNA occur in the 50S complex. Formation of the 50S complex requires the association of a functional RF DNA template with a 108S capsomeric structure containing the protein products of genes D, F, G and H (ref. 10). The functions of genes B and C are also required for formation of the 50S complex. The gene B protein is necessary to catalyse assembly of gene F and gene G proteins<sup>11</sup> to form a precursor of the 108S structure<sup>10-12</sup>. In the absence of gene C protein, the 108S structure is produced but the 50S complex is not formed<sup>10</sup>. Apparently, RF DNA cannot act as a functional template for formation of the 50S complex and, consequently, for synthesis of single-stranded DNA if the gene C protein is absent. To elucidate the function of  $\Phi$ X-174-coded proteins during phage morphogenesis and single-stranded DNA synthesis, we have developed an *in vitro* system that synthesises circular, single-stranded viral DNA<sup>13</sup>. The system contained an extract prepared from cells infected with a lysis-defective mutant of  $\Phi$ X-174. We show here that synthesis of circular viral DNA in the system does depend on the functions of the proteins encoded by  $\Phi$ X-174 genes B and C. The circular single-stranded viral DNA synthesised *in vitro* is contained in infectious particles whose appearance is very much like that of mature  $\Phi$ X-174 phage particles when examined by electron microscopy.

To test the requirement for gene B and gene C proteins we performed an *in vitro* complementation experiment. Cell extracts were prepared from *E. coli* H570-22 (*Su<sup>-</sup>*) that had been infected with either a  $\Phi$ X-174 double mutant (*och11 am3*)<sup>14</sup> of gene C (*ochre*) and gene E (*amber*) or  $\Phi$ X-174 double mutant (*och12 am3*)<sup>14</sup> of gene C (*ochre*) and gene E (*amber*). The amber mutation in the lysis gene E was present for technical reasons and has no effect on phage DNA replication or morphogenesis. *In vitro* complementation can be performed by mixing infected cell extracts directly in the *in vitro* system but the complementary activity of such a system seems to be limited by a deficiency of phage-specific proteins. In order to increase the activity of the *in vitro* reaction, a fraction (fraction 1) enriched in  $\Phi$ X-174-specific proteins was prepared from infected cell extracts by precipitation with  $(\text{NH}_4)_2\text{SO}_4$ . *In vitro* reaction mixtures were prepared using the four possible combinations of cell extract and fraction 1, incubated with radioactive dTTP and analysed by sucrose gradient centrifugation. The two reaction mixtures containing homologous combinations of extract and fraction 1 incorporated dTTP only into material sedimenting at 20S (Fig. 1c, d). The 20S material consisted of only RF DNA<sup>13</sup>. No single-stranded DNA was synthesised in these two reaction mixtures which lack either gene B protein or gene C protein. In contrast, the two reaction mixtures containing heterologous

combinations of extract and fraction 1 incorporated dTTP not only in material sedimenting at 20S but also at 50S and 110S (Fig. 1a, b). Sedimentation analysis, in an alkaline sucrose gradient, of DNA isolated from the 110S material showed that the DNA consisted almost entirely of single-stranded circular DNA of unit-genome size (data not shown).

To determine infectivity associated with 110S material, DNA in the 110S material was density-labelled. A reaction mixture containing extracts and fraction 1 was prepared from both *Och11am3* infected cells and *Och12am3* infected cells and was incubated with BrdUTP substituted for dTTP. Figure 2a shows analysis by sucrose-gradient sedimentation of the products.

**Fig. 1** Sedimentation analysis of *in vitro* product by sucrose gradient centrifugation. *E. coli* H570-22 was infected with  $\Phi$ X-174 *Och11am3* or with *Och12am3*. Infected cells were collected and washed as described previously<sup>13</sup>. The washed cells were suspended in buffer A (50 mM Tris-HCl, 0.1 mM EDTA, pH 7.3, at 25 °C) containing 10% sucrose and 100 mM KCl and cell extracts were prepared. Saturated  $(\text{NH}_4)_2\text{SO}_4$  (in 50 mM Tris-HCl, 1 mM EDTA, pH 7.5) was added to the cell extract (0.8 ml) to 40% saturation, and the mixture was left at 0 °C for 30 min. The precipitate was collected by centrifugation at 18,000g for 20 min. The pellet was suspended in 0.1 ml of buffer B (20 mM Tris-HCl, 1 mM MgCl<sub>2</sub>, 1 mM dithiothreitol, 10% sucrose, 50 mM KCl, pH 7.5 at 0 °C) and dialysed for 3 h against three changes of 125 ml of buffer B. The dialysed fraction is termed fraction 1. Fraction 1 contained about 20 mg of protein per ml. A standard reaction mixture (0.25 ml) contained 0.14 ml of cell extract, 20  $\mu$ l of fraction 1, 50 mM Tris-HCl, pH 7.1 at 30 °C, 0.1 mM each dATP, dCTP, dGTP and  $\alpha^{32}\text{P}$ -dTTP (150–500 c.p.m.  $\mu\text{mol}^{-1}$ ), 0.1 mM each CTP, UTP, GTP, 0.2 mM ATP, 0.2 mM NAD, 15 mM MgCl<sub>2</sub>, 10 mM  $\beta$ -mercaptoethanol, 500  $\mu\text{g ml}^{-1}$  bovine serum albumin (BSA) and 80  $\mu\text{g ml}^{-1}$  rifampicin. Reaction mixtures were incubated at 30 °C for 18 min. A complete reaction mixture (in 62.5  $\mu$ l) ( $\alpha^{32}\text{P}$ -dTTP 220 c.p.m.  $\mu\text{mol}^{-1}$ ) containing a, 35  $\mu$ l of extract from *Och11am3* infected cells and 10  $\mu$ l of fraction 1 from *Och12am3* infected cells; b, 35  $\mu$ l of extract from *Och12am3* infected cells and 10  $\mu$ l of fraction 1 from *Och11am3* infected cells; c, 35  $\mu$ l of the extract, 10  $\mu$ l of fraction 1 both from *Och11am3* infected cells; or d, 35  $\mu$ l of the extract and 10  $\mu$ l of fraction 1 both from *Och12am3* infected cells was incubated at 30 °C for 18 min. The reaction was stopped by the addition of 150  $\mu$ l of ice-cold buffer C (50 mM Tris-HCl, 100 mM KCl, 15 mM EDTA and 500  $\mu\text{g ml}^{-1}$  BSA, pH 7.5 at 0 °C).  $^3\text{H}$ -Thymidine-labelled mature phage was added as a marker and 200  $\mu$ l of the diluted reaction mixture was layered onto a sucrose gradient (15–30% in 10 mM Tris-HCl, pH 7.25 at 25 °C, 100 mM NaCl, 5 mM EDTA and 3.5% CsCl with a 0.15 ml cushion of 55% CsCl and 50% sucrose at the bottom of the gradient). Sucrose gradient was centrifuged in Beckman SW50.1 rotor at 49,000 r.p.m. for 70 min at 0 °C. Fractions were collected onto squares of Whatman 3 MM filter paper which were washed with trichloroacetic acid (TCA) and ethanol, dried and counted. Fractions 37 to 40 were discarded because these fractions did not contain TCA-insoluble material. ●,  $^{32}\text{P}$  c.p.m.; ×,  $^3\text{H}$  c.p.m.

The fractions containing density-labelled 110S material (fractions 5 to 8) from the sucrose gradient shown in Fig. 2a were combined and subjected to buoyant density centrifugation in CsCl. The 110S material banded in a single peak at a density of  $1.45 \text{ g ml}^{-1}$  while mature phage particles not containing BrdUMP banded at a density of  $1.41 \text{ g ml}^{-1}$  (Fig. 2b). When each fraction of the CsCl gradient was titred using *E. coli* Su20c (*Su*<sup>+</sup>) as the indicator, a peak of infectivity which coincided exactly with the peak of radioactivity at the density of  $1.45 \text{ g ml}^{-1}$  was found. This peak of infectious material synthesised *in vitro* contained particles that were indistinguishable from mature phage particles when examined in an electron microscope (Fig. 3).

Infectious but non-radioactive material was found at densities equal to and less than the density of marker phage particles (Fig. 2b). This material was also present in *in vitro* reaction

**Fig. 2** Analysis of *in vitro* products labelled with BrdUTP. **a**, A reaction mixture (125  $\mu\text{l}$ ) containing 35  $\mu\text{l}$  of extract and 10  $\mu\text{l}$  of fraction 1 from *Och11am3* infected cells and 35  $\mu\text{l}$  of extract and 10  $\mu\text{l}$  of fraction 1 from *Och12am3* infected cells was incubated for 18 min at  $30^\circ\text{C}$ . The other components of the reaction mixture were as described in the legend to Fig. 1 except that dTTP and dATP were replaced by 0.1 mM BrdUTP and 0.1 mM  $^3\text{H}$ -dATP (440 c.p.m.  $\text{pmol}^{-1}$ ) respectively. The reaction was stopped by the addition of 0.5 ml of buffer C. Ultraviolet-irradiated  $^{14}\text{C}$ -marker phage was added to the reaction mixture which was analysed by sucrose gradient centrifugation (5 to 30%, ref. 13) at 49,000 r.p.m. at  $0^\circ\text{C}$  for 50 min.  $\bullet$ ,  $^3\text{H}$ ;  $\times$ ,  $^{14}\text{C}$ . **b**, Fractions 5 to 8 of the sucrose gradient shown in (a) were pooled and 2.2 g of CsCl and 3.1 ml of Na borate buffer (50 mM sodium tetraborate, 5 mM EDTA) were added to 1.05 ml of the pooled material which was dialysed against the borate buffer. Centrifugation was performed at 33,000 r.p.m. for 44 h at  $10^\circ\text{C}$ . Fractions were collected from the bottom of the centrifuge tubes. 10  $\mu\text{l}$  of each fraction was assayed for radioactivity. The infectivity of each fraction was determined by plaque assay using *E. coli* Su20c (*Su*<sup>+</sup>) as indicator.  $\bullet$ ,  $^3\text{H}$ ;  $\times$ ,  $^{14}\text{C}$ ;  $\circ$ , infectivity (PFU per ml);  $\blacksquare$ , density ( $\text{g ml}^{-1}$ ). **c**, A reaction mixture (62.5  $\mu\text{l}$ ) containing 35  $\mu\text{l}$  of extract and 10  $\mu\text{l}$  of fraction 1 from *Och11am3* infected cells and another reaction mixture (62.5  $\mu\text{l}$ ) containing 35  $\mu\text{l}$  of extract and 10  $\mu\text{l}$  of fraction 1 from *Och12am3* infected cells were prepared as detailed in (a), and incubated separately for 18 min at  $30^\circ\text{C}$ . The reactions were stopped by adding 0.25 ml of ice-cold buffer C to each tube. Then, the two reaction mixtures were combined and centrifuged in a sucrose gradient as described in (a). Fractions 5 to 8 of the sucrose gradient were pooled and analysed by CsCl buoyant density centrifugation as described in (b).  $\times$ ,  $^{14}\text{C}$ -marker phage;  $\circ$ , infectivity (PFU per ml);  $\blacksquare$ , density ( $\text{g ml}^{-1}$ ).

mixtures in the absence of complementation (Fig. 2c). Since no material labelled *in vitro* was seen at these densities, the low density infectious material apparently existed in the infected cell extracts and might be due to unclipped phages that were recovered from infected cells in the extracts and/or fraction 1.

Several observations indicate that synthesis and packaging of  $\Phi\text{X-174}$  single-stranded DNA by our *in vitro* system proceed by mechanisms very similar to those that occur *in vivo*. Our previous results suggest that single-stranded DNA synthesis *in vitro* involves the 50S complex containing  $\sigma$  structure DNA<sup>13</sup> and that the *in vitro* 50S complex is a precursor of a particle containing circular single-stranded DNA<sup>13</sup>. We have shown here *de novo* synthesis of single-stranded viral DNA via the 50S complex by complementation experiments (Fig. 1). The synthesised single-stranded DNA is packaged in particles that are infectious and are similar in appearance to mature phage

**Fig. 3** Electron micrographs of 110S particles. Preparations of mature phages or density-labelled 110S particles (Fig. 2b) containing  $1-3 \times 10^{11}$  particles per ml were negatively stained with 2% neutral potassium phosphotungstate. **a**, Mature phages; **b**, 110S particles. Scale bar, 100 nm.

particles in the electron microscope. Further studies are required to determine the differences between 110S *in vitro* particles and 114S *in vivo* mature phages. The *in vitro* complementation system for synthesis of infectious  $\Phi$ X-174 particles described here may provide a new way of studying the interaction of viral components during phage morphogenesis.

We thank Dr F. Fujimura and Mrs M. Hayashi for discussions, Dr F. D. Funk for providing mutant phages and Mr P. Kammerer for technical assistance. This work was supported by USNSF and NIH grants.

## Extensive reverse transcription of RSV genome by nucleic acid-binding protein

THE discovery of reverse transcriptase<sup>1,2</sup> offered the possibility of using *in vitro* synthesis to study the replication of RNA tumour virus genomes in molecular detail. Attempts to study DNA provirus formation *in vitro*, however, have encountered serious obstacles: poor efficiency of transcription, small DNA products, and unequal representation of the viral RNA sequences in the DNA product have been common findings<sup>3</sup>. These difficulties in copying RNA into DNA have led to suggestions that cellular factors, such as ligases or unwinding proteins might be necessary to assist reverse transcriptase in copying the viral RNA genome into a complete DNA transcript<sup>4,5</sup>.

Binding (unwinding) proteins involved in DNA synthesis are well known in bacteria<sup>6,7</sup> and have also been described in mammalian systems<sup>8</sup>. We reported previously the isolation of a DNA binding protein from transformed chicken cells and its stimulating effect on reverse transcriptase activities<sup>5</sup>. Here we present evidence that, in the presence of the binding protein, purified reverse transcriptase from Rous sarcoma virus (RSV) synthesised an extensive, possibly complete complementary transcript of DNA from the viral RNA genome in a totally reconstituted reaction system.

RSV-transformed chicken fibroblasts were sonicated and its nucleic acids were removed by polyethylene glycol precipitation in high salt as reported previously<sup>9</sup>. The supernatant was then loaded on a single-stranded DNA-cellulose column and the binding activity eluted with 0.2 M NaCl was further passed through DEAE-cellulose and then to a CM BioGel (BioRad) column. A single peak of binding activity as measured by the membrane filtration technique<sup>9</sup> was eluted from the CM BioGel column at 0.3 M NaCl in a buffer containing 0.05 M Tris-HCl, pH 8.1, 10% glycerol, 1 mM 2-mercaptoethanol, and 1 mM EDTA. This material showed a major Coomassie blue band of over 85% homogeneity corresponding to a molecular weight of about 30,000. One microgram of the purified protein was capable of increased binding to 16  $\mu$ g of <sup>3</sup>H-poly (dA,dT) and thus at least a 500-fold enrichment in the nucleic acid binding activity was obtained from the crude sonicated extract. It had no detectable reverse transcriptase, DNA polymerase or nuclease activities when analysed<sup>10-12</sup>. Detailed isolation procedures will be published elsewhere. The binding protein was able to bind to various synthetic polynucleotides as well as to 70S <sup>3</sup>H-RSV RNA. Figure 1a and b shows the binding activity profiles when 70S <sup>3</sup>H-RSV RNA and <sup>3</sup>H-poly(A,U) were used as the substrates. The amount of binding as indicated by radioactivity retained on the membrane increased linearly until the protein saturated the binding capacity. It was calculated that at the saturation point one binding protein molecule covered 10 nucleotide bases in these substrates. Since the protein showed different rates in binding to various nucleic acids (unpublished observation), we studied the affinity of the protein to a few kinds of nucleic acid in environments of increasing ionic strength. Figure 2 shows the results of the binding study at different NaCl concentrations. There were significant decreases in binding of the protein to <sup>3</sup>H-poly A, <sup>3</sup>H-poly(A,U) and <sup>3</sup>H-poly

Fig. 1. Nucleic acid-binding activities of the binding protein as a function of its concentration. The assay measured the amount of radioactive nucleic acid bound to nitrocellulose filters<sup>9</sup> in the presence of the binding protein. The binding buffer contained 0.02 M Tris-HCl (pH 8.1), 1 mM EDTA, 1 mM 2-mercaptoethanol, 0.02 M NaCl and 5% glycerol. After incubation at 37 °C for 10 min in a total volume of 0.1 ml, the reaction mixture was chilled, diluted and filtered through a Millipore nitrocellulose filter (type HA 0.45  $\mu$ m). The filter was washed with the binding buffer, dried and the radioactivity determined in a toluene-based scintillation fluid. The binding substrates: a, 70S <sup>3</sup>H-RSV RNA (0.2  $\mu$ g, 20,000 c.p.m.  $\mu$ g<sup>-1</sup>); b, poly(<sup>3</sup>H-A,U) (0.1  $\mu$ Ci; 34 mCi per mmol phosphate).

**Fig. 2** Effects of ionic strength on the binding of the protein to various nucleic acids. The buffer used during binding and washing was the same as described in Fig. 1, except that the concentration of NaCl varied as indicated. The binding in the absence of NaCl was taken as 100%. ○, 70S <sup>3</sup>H-RSV RNA (0.2 μg, 20,000 c.p.m. μg<sup>-1</sup>); ●, <sup>3</sup>H-poly A (0.1 μCi; 25 mCi; per mmol per mmol phosphate); △, poly(<sup>3</sup>H-A,U) (0.1 μCi; 34 mCi per mmol phosphate); □, <sup>3</sup>H-poly(dA, dT) (0.1 μCi; 22 mCi per mmol phosphate). Radioactive synthetic polynucleotides were obtained from Miles.

(dA,dT) when NaCl concentration was increased to 0.05 M or higher. The binding to 70S <sup>3</sup>H-RSV RNA by the protein decreased only 10% at 0.2 M NaCl, however. It is possible that some specific nucleic acid sequences in the RSV RNA have a high affinity to the binding protein and thus make the complex more resistant to dissociation in higher ionic strength. An additional piece of evidence to substantiate that the binding protein interacts with nucleic acid was provided by the following study. It is well known that the single-stranded viral RNA contains considerable secondary structures with certain regions of the genome intramolecularly hydrogen-bonded<sup>13</sup>. Therefore we studied the unwinding of this highly structured RNA by the binding protein by measuring ultraviolet hyperchromicity

**Fig. 3** Unwinding of the 70S RSV RNA by the binding protein. The reaction mixture contained 70S RSV RNA (1.6 μg) and the binding protein (15 μg) in 0.5 ml of 0.05M Tris-HCl (pH 8.1), 0.02 M NaCl, 1 mM 2-mercaptoethanol, 1 mM EDTA and 30% glycerol. Binding protein and the RNA were mixed at time zero, and  $A_{260}$  was determined with a recording Gilford Spectrophotometer at 24 °C. Solutions of the binding protein or the RNA alone in the same buffer were scanned at the same time as controls—no changes in absorbance were observed.

which is characteristic of the helix-coil transition<sup>14</sup>. The result of such an experiment is shown in Fig. 3. The absorption at 260 nm of 70S RSV RNA increased 15–20% in less than 1 min after the addition of the binding protein at 24 °C and this suggested a fast unwinding of RSV RNA by the binding protein. The hyperchromic effect was reversible on addition of NaCl to 0.6 M (Fig. 3) suggesting that the RNA was deproteinated and returned to the folded structure.

Because of the closeness of the natural primer to the 5' terminus of RSV RNA (refs 15, 16) and of the great secondary structure of the RNA, *in vitro* DNA synthesis can only proceed to a limited distance along the template and result in small DNA products<sup>5</sup>. We therefore attempted to remedy these two difficulties during reverse transcription by, first, using (dT)<sub>12-18</sub> as the primer to start DNA synthesis from the 3' terminus<sup>17</sup> and, second, by adding the binding protein to melt the hydrogen-bonded regions. DNA was synthesised in a totally reconstituted system containing purified 70S RSV RNA (ref. 18), reverse transcriptase<sup>18</sup>, dATP, dGTP, dCTP, Mg<sup>2+</sup>, <sup>32</sup>P-TTP, (dT)<sub>12-18</sub> and actinomycin D as described in Fig. 4. After incubation the reaction was stopped by EDTA and passed through a Sephadex G-50 column, DNA in the void volume was ethanol-precipitated, alkaline-hydrolysed and analysed by Agarose gel electrophoresis<sup>19</sup>. The results of the experiment are shown by autoradiography in Fig. 4. Lane 1 shows that when no binding protein was added most DNA products moved to the far end of the gel corresponding to a mobility of about 4S.

**Table 1** Hybridisation of DNA products with 70S RSV RNA

Sample	70S RSV RNA	Acid-precipitable radioactivity (c.p.m.)	Resistant fraction (%)
Control (minus S <sub>1</sub> nuclease)	—	1,120	100
Self-annealing (plus S <sub>1</sub> nuclease)	—	71	6
Hybridisation (plus S <sub>1</sub> nuclease)	+	1,066	95

Radioactive DNA was prepared as described in Fig. 4, lane 2. DNA samples were hybridised in 2×SSC at 68 °C for 2 h in a total volume of 20 μl. When 70S RSV RNA (2 μg) was used, the ratio of RNA to DNA was estimated to be over 1,000. Resistance to S<sub>1</sub> nuclease was determined by incubating an aliquot of the incubation mixture for 2 h at 37 °C in 1 mM ZnSO<sub>4</sub>, 0.1 M sodium acetate (pH 5.0), and 2,000 units of S<sub>1</sub> nuclease, when used. The nuclease-resistant DNA was recovered as trichloroacetic acid-precipitable counts with 10 μg of salmon sperm DNA as carrier.

In lanes 2, 3 and 4 with various preparations of binding protein added, almost all of the DNA product moved much slower and its mobility corresponded to that of 35S RSV RNA. The appearance of the large products in lane 2, 3 and 4 was eliminated if the binding protein solution was first heated to 65 °C for 10 min (not shown here). To confirm that the radioactive product which corresponded to 35S in electrophoretic mobility was indeed complementary to 70S RSV RNA, we annealed the DNA product to the RNA template and digested the unreacted DNA with nuclease S<sub>1</sub> (ref. 20). Table 1 shows that 95% of radioactivity in the DNA product was resistant to the digestion after it had hybridised to 70S RSV RNA whereas DNA by itself was sensitive to the nuclease. This strongly suggested that the product was a single-stranded DNA with homology to the viral RNA genome.

The results presented here show that reverse transcriptase from RSV is able to synthesise, in a reconstructed system, a complete or nearly complete DNA copy from the purified viral RNA in the presence of the binding protein isolated

from chicken cells. There are many advantages in being able to make a complete cDNA in a totally reconstructed system. The long, representative DNA transcripts of tumour viral RNA provide a source of excellent probes for molecular hybridisation. By controlling components of the *in vitro* reaction one at a time, we can obtain a molecular detail of the mechanism of complete reverse transcription.

Although many investigators attempted to synthesise the complete cDNA from tumour virus RNA in a purified enzyme system, the DNA product was always considerably smaller than the template<sup>3</sup>. In some cases, there was faithful representation of the sequence information in the RNA,

**Fig. 4** Autoradiography of DNA products synthesised *in vitro* by reverse transcriptase. Incubation mixtures (0.1 ml) contained the following: 0.05 M Tris-HCl, pH 8.3, 0.06 M KCl, 5 mM MgCl<sub>2</sub>, 0.01 M dithiothreitol, 0.1 mM EDTA, 0.02% NP-40, 1.6 µg 70S RSV RNA, 0.1 µg (dT)<sub>10-18</sub>, 100 µg ml<sup>-1</sup> actinomycin D, 0.1 mM each of dATP, dCTP, dGTP, 10 µCi [ $\alpha$ -<sup>32</sup>P]TTP, (1 Ci mmol<sup>-1</sup>), 20 units of reverse transcriptase purified by the method of Grandgenett *et al.*<sup>10</sup>. The reaction mixture was incubated at 37 °C for 10 min, and then binding protein or buffer alone was added. Lane 1, buffer control. Lane 2, 4 µg of binding protein from a preparation of transformed cells. Lane 3, 4 µg from another transformed cell preparation. Lane 4, 15 µg of binding protein from non-transformed cells. Incubation was carried out further at 24 °C for 4 h. At the end of the incubation, the reaction mixture was adjusted to contain 0.05 M EDTA, 0.2% sodium sarkosyl and 50 µg yeast RNA. The DNA product was isolated by Sephadex filtration and alkali hydrolysis according to Rothenberg and Baltimore<sup>19</sup>. The samples thus obtained were divided into two parts, one for electrophoresis followed by autoradiography and the other, for hybridisation studies. Electrophoresis of the DNA products (approximately 1,000 c.p.m. per slot) was done in 0.8% Agarose gel (10 cm long) for 3.5 h at 100 V (ref. 25). Non-radioactive 70S RSV RNA, 35S RSV RNA obtained by heating and chilling of 70S (ref. 26) and tRNA were co-electrophoresed. Ethidium bromide was used to stain these markers after the electrophoresis and arrows indicate their positions. The gel was dried and autoradiographed as described by Maizel *et al.*<sup>27</sup>.

but only a small portion of the template was represented in a greatly disproportionated amount<sup>19,21,22</sup>. The incomplete cDNA transcripts of the RSV RNA occurred as discrete size classes rather than a continuous array of decreasing sizes<sup>23</sup>. This suggested that when reverse transcriptase started DNA synthesis at the primer and transcribed along the single-stranded RNA, it could encounter hairpin loops or other forms of secondary structure present in the viral RNA at one or more points, thereby resulting in a partial blockage of transcription or in dissociation of the enzyme at these discrete sites. The nucleic acid-binding protein, by virtue of its ability to bind and unwind the RNA molecule

(Figs 1 and 3), can hold the RNA in a rigid, extended conformation which affords a favourable configuration for reverse transcriptase to continue the cDNA synthesis instead of coming to a stop at the hairpin loops. We believe that the affinity of the binding protein to RSV RNA is such that when reverse transcriptase moves along the template, it replaces the binding protein to continue cDNA synthesis. This was supported by evidence shown in Fig. 5 that reverse

**Fig. 5** Effect of ionic strength on the binding of reverse transcriptase to various nucleic acids. The buffer used during binding and washing was the same as described in Fig. 1, except that the concentration of NaCl varied as indicated. Binding of reverse transcriptase (5 units) to the substrate in the absence of NaCl was taken as 100%. ●, 70S <sup>3</sup>H-RSV RNA (0.2 µg; 20,000 c.p.m. µg<sup>-1</sup>); ×, <sup>3</sup>H-poly U (0.1 µCi; 30 mCi per mmol phosphate); △, poly(<sup>3</sup>H-A, U) (0.1 µCi; 34 mCi per mmol phosphate).

transcriptase bound to RSV RNA much tighter than the binding protein. In this experiment, the binding of reverse transcriptase to 70S RSV RNA increased twice at ionic strengths as high as 1.0 M NaCl, in contrast to a gradual dissociation of the binding protein from RSV RNA at higher ionic strength (Fig. 2).

Although the binding protein reported here was purified from RSV-transformed chick cells, the protein did not seem to be coded by the virus. In a preliminary study we also detected a binding protein of similar properties in normal chicken cells (Fig. 4, lane 4). A viral protein binding tightly to the viral RNA has been recently found in the RSV viral core<sup>24</sup>. This viral core protein formed such a tight complex with the viral RNA that it inhibited rather than stimulated reverse transcription (J. Leis, personal communication).

We are now characterising the DNA product in more detail. It will be of great interest to synthesise a DNA duplex (provirus) of the whole viral genome and study its infectivity as well as nucleotide sequences of the fragments obtained from restriction enzymes.

We thank W. Schulze for technical assistance.

## 2-Aminoadenine is an adenine substituting for a base in S-2L cyanophage DNA

THE properties of DNA from viruses acting on blue-green algae (cyanophages) have been studied in only a few instances<sup>1,2</sup>. It is not known whether these DNA molecules contain any unusual bases<sup>3–7</sup> or some modified (methylated) bases known to be present in DNA of many prokaryotes and to be specific for host modification and restriction phenomena. Here we report the isolation and identification of the base 2-aminoadenine and its deoxyribonucleoside from S-2L cyanophage DNA. Some unusual properties of this DNA in which adenine is completely substituted with 2-aminoadenine are described.

Cyanophage S-2L was isolated from water samples taken in the outskirts of Leningrad. It can lyse blue-green algae *Synechococcus* sp. 698 and *S. elongatus* strains 58 and 6907 (from the collection of the Biology Institute, Leningrad State University). The phage was grown on *S. sp.* 698 and concentrated by chromatography on DEAE-cellulose (Whatman DE-32) and purified by centrifugation in CsCl gradient<sup>2,8</sup>. The phage consists of an icosahedral head, 56 nm in diameter, with a flexible non-contractile tail 120 nm long and 10 nm thick. S-2L phage is morphologically similar to SM-2 cyanophage<sup>9</sup>.

The nucleic acid of phage S-2L is linear double-stranded DNA. It reacts typically for deoxyribose with a diphenylamine-containing reagent according to Dische; it is not hydrolysed in

alkali (0.7 M NaOH, 18 h at 37 °C) or with pancreatic RNase. The mean contour length of S-2L DNA molecules prepared according to Kleinschmidt<sup>10</sup> was  $14.4 \pm 0.5 \mu\text{m}$ , corresponding to a molecular weight<sup>11</sup> of  $28 \pm 0.5 \times 10^6$ . The average value for  $S_{20,w}^{0}$  for S-2L DNA was  $32.5 \pm 0.3 S$ —a molecular weight value<sup>12</sup> of  $26 \pm 1 \times 10^6$ .

The buoyant density of S-2L DNA, relative to *Escherichia coli* B DNA ( $\rho = 1.7109 \text{ g cm}^{-3}$ ) was found to be  $1.731 \text{ g cm}^{-3}$ . When S-2L DNA was centrifuged with *Micrococcus lysodeikticus* DNA ( $\rho = 1.731 \text{ g cm}^{-3}$ ), a single symmetric ultraviolet absorbing peak was observed.

The hyperchromic value of S-2L DNA at 260 nm is 27–29%, at 280 nm it reaches 50% (Fig. 1);  $T_m$  in 0.1 SSC is 85.6 °C; in 0.01 M sodium phosphate buffer pH 7.0, 0.001 M Na<sub>2</sub> EDTA  $T_m$  is 84.3 °C. The DNA melts within a small temperature range ( $\Delta T_m = 3^\circ\text{C}$ ) which is typical of homogenous viral DNA. A characteristic feature of native S-2L DNA is the unusually low spectral ratio ( $A_{\text{max}}/A_{\text{min}} = 1.6$ ,  $A_{260}/A_{230} = 1.5$ ,  $A_{260}/A_{280} = 1.75$ ).

In contrast to the circular dichroism (CD) spectrum of usual natural DNA that possesses a single positive band at 276 nm, S-2L DNA has two almost equal positive bands, at 290 nm and 265 nm, (Fig. 2). This very characteristic CD spectrum and the other unusual ultraviolet spectral properties strongly suggest the presence of some unusual base in S-2L phage DNA.

Fig. 1 S-2L phage DNA absorption spectrum in 0.1 SSC; a, at 20 °C and b, at 90 °C.

Fig. 2 CD spectrum of S-2L phage DNA in 0.01 M phosphate buffer, pH 7.0–0.001 M Na<sub>2</sub>-EDTA (1.3 absorbance units at 260 nm per ml).

For determination of the base composition, the DNA was hydrolysed into bases by 57% HClO<sub>4</sub> (100 °C, 1 h) or 99% HCOOH (176 °C, 1 h). Bases were separated by thin layer chromatography (TLC) (Fixion 50 × 8 cation exchanger (Chinoin) in 2.8 M HCl)<sup>13</sup>; as well as thymine, cytosine and guanine, a fourth base with the lowest  $R_f$  value, was present. This base was purified by TLC on cellulose (Filtrak) in different solvent systems. The isolated base shows intensive blue fluorescence in ultraviolet light and a characteristic ultraviolet adsorption spectrum (two maxima); the base has the same spectral (Fig. 3, Table 1) and chromatographic properties as authentic 2-aminoadenine (Chemapol). On bromination the base degrades—like 2-aminoadenine and unlike adenine (Fig. 3).

Complete enzymatic hydrolysis of S-2L DNA to nucleosides, yielded 2-aminoadenine deoxyribonucleoside after two-dimensional TLC of deoxyribonucleosides on cellulose<sup>14</sup>. The ultraviolet and fluorescence spectra of the 2-aminoadenine deoxyribonucleoside isolated were identical to those reported for

\*Isolated from hydrolysed phage DNA by two-dimensional TLC on cellulose (Filtrak)<sup>14</sup>.

†Isolated by TLC on Fixion 50 × 8 in 2.8 M HCl<sup>13</sup>, repeated TLC on cellulose (Filtrak) in isopropanol–11 M HCl–H<sub>2</sub>O (170:45:35 v/v) and then repeated TLC in the solvent systems *n*-butanol–H<sub>2</sub>O–25% NH<sub>4</sub>OH (60:10:0.1 v/v); isopropanol–H<sub>2</sub>O (70:30), NH<sub>3</sub> in gas phase; *n*-butanol–5 M acetic acid (2:1 v/v).

2-aminoadenosine<sup>15</sup>. Thus, S-2L phage DNA contains 2-aminoadenine, guanine, cytosine and thymine; no other bases were found. DNA of host alga *Synechococcus* sp. 698 contains usual bases, including adenine, rather than 2-aminoadenine, and its GC content is 70.0 mol %.

On complete enzymatic hydrolysis the S-2L DNA was found to contain (mol %): 2-aminoadenine deoxyribonucleoside, 15.9 ± 0.5; deoxythymidine, 15.4 ± 0.1; deoxycytidine, 34.4 ± 0.4 and deoxyguanosine, 34.3 ± 0.3. This DNA thus contains equimolar quantities of 2-aminoadenine and thymine and of guanine and cytosine.

The presence of the additional amino group in 2-aminoadenine as compared to adenine permits formation of the three hydrogen bonds in 2-aminoadenine–thymine base pair<sup>16</sup>. This seems to account for the higher  $T_m$  (85.6 °C, in 0.1 × SSC) for 2-aminoadenine containing S-2L DNA as compared with usual adenine-containing DNA ( $T_m$  = 82.0 °C) which is equivalent to

the former in GC content. According to the  $T_m$  value, S-2L DNA should contain 77.4 mol % of GC, since from the  $\rho$  value (1.731 g cm<sup>-3</sup>) the GC content should be 72.5 mol %<sup>17,18</sup>; in fact the DNA contains only 68.7 mol % of GC.

The anomalous CD spectrum of S-2L DNA is similar to the CD spectrum of polyribodiaminopurine–poly U complex<sup>19</sup>, the difference being only in the sign of the bands at 290 nm. Dichroism measurements may therefore prove useful for the possible detection of 2-aminoadenine in other viral nucleic acids.

In contrast to other viruses containing novel bases substituting for ordinary pyrimidines<sup>3–7</sup>, S-2L phage seems to be the first case in which one of the ordinary purine bases in DNA is completely substituted with a modified base. It seems likely that 2-aminoadenine incorporates into S-2L phage DNA as a ready-made nucleotide, rather than forming at the polynucleotide level as a result of amination of adenine residues in DNA. In cells of virus-infected blue-green algae new paths for the synthesis of the adenine nucleotide derivative may therefore exist: a special system for regulation and discrimination between the replication of host and unusual 2-aminoadenine-containing viral DNA would be needed.

**Fig. 3** Ultraviolet spectra of the base and its deoxyribonucleoside isolated from S-2L phage DNA. *a*, Base in 0.1 M HCl; *b*, base in 0.1 M KOH; *c*, base after bromination; *d*, deoxyribonucleoside in 0.05 M K-phosphate buffer, pH 6.7.

## Tectonic changes in global terms

D. H. Tarling

*The Evolving Continents.* By Brian F. Windley. Pp. xviii + 385. (Wiley: London and New York, 1977.) £14; \$28.

THIS is, without doubt, one of the best of recent books concerned with the Earth's evolution and is the first which really does attempt to see tectonic changes in terms of the total history of the Earth. At last, the Precambrian has been treated as an integral part of the Earth instead of being confined either to specialist books or to forming the odd paragraph added on to an evolutionary story that is otherwise entirely concerned with the Phanerozoic. It would be ingenuous to fault different parts of the book for lack of sufficient data or for inadequate coverage of general ideas, and any such criticism must be considered secondary to the real achievement of combining an optimum of both information and ideas within less than 400 pages.

The level is essentially for third year undergraduates and upwards and should form a standard advanced text, following an Arthur Holmes introduction to the earth sciences, although some amplification of plate tectonic terminology will be needed—lithosphere is, for example, not defined, but it is certainly useful to have the Burke-Dewey "aulacogen" described fully, as this term is still not in most dictionaries. The lack of definition of lithosphere compared with that for aulacogen, in fact, reflects the essentially geological-geochemical approach throughout, with the geophysics largely restricted to palaeomagnetism. Nonetheless, to complain about this lack of geophysical content is, to some extent, unfair, as sufficient books have appeared recently on geophysical plate tectonics in the Phanerozoic to sate most people's appetites.

Precambrian geology and models comprise half of the book with the Phanerozoic and generalities forming the remaining half. Logically, it starts with the Archaean, with one chapter on high grade terranes; one on low grade; and a third is concerned with models of Archaean crustal evolution. The Proterozoic takes a little longer, with four chapters preceding the summary of crustal evolutionary models for this period. The ability to condense the Archaean better than the Proterozoic

possibly reflects Windley's previous background, but it must be stressed that meaningful generalisations about the evolution of Proterozoic regimes have previously been virtually restricted to the publications of Sutton and Watson.

Naturally, such an initial compilation of information and ideas can be criticised in numerous places, although Windley often plays safe by outlining other people's descriptions without significant critical comment. This is understandable in relation to 'factual' observations, but is less satisfactory where ideas are presented and discussed. Albeit rarely, Windley's views sometimes tend to bias the presentation of other schema. Criticism is always possible on the detail of the coverage—half-a-page on the West Australian Kalgoorlie System is barely sufficient to provide references; and this is virtually all it does. But any real extensions would have doubled the size of the book and probably more than doubled its price.

The second half, dealing with the generally accepted Phanerozoic plate tectonics, is less successful, and it is arguable as to the extent to which it could be both reduced and expanded. There are three chapters on orogenic belts—Caledonian, Hercynian and Alpine—which illustrate this point. The Caledonian chapter could well be reduced, as this is described well elsewhere. The Alpine chapter is so abbreviated as to be virtually notes against which a specialist could view his own area or interest, but they are too skeletal for the undergraduate. The chapter on Hercynian is sufficiently short to reflect the surprising lack of interest by most geologists in this period, but does not adequately represent the multiplicity of views which interested earth scientists have expressed. All three, as usual, also suffer from a parochial 'Laurentian' view, with no consideration of the extension of such systems into, for example, Asia.

The second half also suffers from an apparent desire to insert as many aspects as possible. It is a pity, for example, that the elementary outline of palaeomagnetism is not severely reduced to provide space for a discussion of how isotopic studies actually

indicate the source for volcanics, as this knowledge is virtually assumed in the opening chapters. Similarly, the treatment of palaeoclimates is so elementary as to be almost unnecessary. Also crammed within this half are the chapters on seafloor spreading, cordilleran mountain chains, palaeontological implications, island arc systems and an outline of the breakup of Pangaea. Some of these chapters tend to side-track, so that the breakup of Pangaea seems to be mostly related to the evolution of volcanic systems rather than the actual history of break up and separation which is again essentially in note form.

One of the other new features of the book is an attempt to introduce sections of the characteristic mineralisation associated with specific times and localities. This aspect clearly reflects the general, increased interest in the applicability of academic research to real problems. Windley is to be congratulated on his attempt, but this is, unfortunately, probably the least satisfactory part—even though this must be considered a major achievement. The problem is probably one of space, as most of the mineralisation sections are fairly bald statements of what minerals occur where, but with inadequate discussion of why they occur in those particular places at those particular times. To some extent such origins may still be unknown and would therefore be highly speculative, but it is disappointing to find that possible causative factors are not adequately discussed. The same is even more true for the appraisal of the changing tectonic processes. Drastically different tectonic regimes are described for the Archaean, Proterozoic and Phanerozoic, but the only causative feature which is described as being different is that of radiogenic heat production within the Earth. This change in heat production with time is quantified, but Windley does not offer any considerations for the implication of such changes to, for example, lithospheric thickness and the major, almost catastrophic, changes in the physical behaviour of the lithospheric plates which occur as such changes took place. In other words, there is really no discussion of the actual mechanisms—discussions of con-

vection are mostly restricted to minor Archaean problems. On this basis, the book tends to be overly concerned with the end-products of mantle processes and virtually ignores the mechanisms by which they are derived, and therefore why their operation may have changed with time. Some discussion of the vertical variation in the continental crust is also required and the way in which these differences have evolved should have been discussed. Reducing some of the side-lines in the second half and really considering the changing mechanism of tectonic change would then have been more consistent with the title.

The production is excellent and the illustrations are ample; in fact almost too many, as several could have been usefully combined. This tends to apply also to the text, where Windley's desire to give other people's views possibly

would have been better presented as a clear statement with references. These features tend to make some parts seem rather too much like lecture notes, with slides of published work, than is desirable. Such comments are, however, intended sympathetically, as it would be hard to improve the text without grossly expanding the total length. Nonetheless, although improvements are possible, particularly in considering the mechanism of tectonic change, this book can be unreservedly recommended to final-year and postgraduate students both as a textbook and a source of references for further studies. It must be an essential on any final-year earth science reading list. □

## Dynamic systems

*Synergetics: An Introduction. Non-Equilibrium Phase Transitions and Self-Organisation in Physics, Chemistry and Biology. By H. Haken. Pp. xii+325. (Springer: Berlin and New York, 1977.) DM72; \$31.70.*

FOR some time now, it has been the main concern of the author to popularise the subject he has chosen to call "synergetics". To most readers, however, this term is less familiar than the subject itself—the theory of phase transitions in co-operative dynamic systems, applied to examples ranging from physics to sociology. Part of the material presented in this book is already contained in several review articles and conference proceedings, but now H. Haken presents in this volume a detailed and comprehensive account of the basic principles and applications of this "interdisciplinary field of research".

The term "synergetics" was prompted by the variety of dynamic systems stemming from physics, chemistry, biology and sociology which show striking similarities at their points of instability. As the book is meant to be a student textbook, the author provides in the first few chapters the mathematical prerequisites. After some introductory sections on probability and information theory, the reader becomes acquainted with stochastic processes (Brownian motion, random walks and their description by Master equations) and deterministic motion (here, the concepts of stability, critical points, hard and soft mode excitations, limit cycles, and so on, are introduced).

The connection between deterministic and stochastic processes (or chance and necessity) is provided by the Fokker-Planck equation approach, which is discussed extensively and used to introduce the Landau theory of phase transitions. Combining all these concepts, the author then explains in a rather formal and abstract way the generation of order by self-organisation. Then, separately, these formal considerations are applied to various examples. Starting from physics (laser and hydrodynamic instabilities), the reader is led to nonlinear chemical reactions (with their showpieces, Brusselator and Oregonator) and biological systems (models for ecology, evolution and morphogenesis); and, finally, a model for interacting social groups is presented.

This book certainly serves its purpose as an introductory student text, as it requires little previous knowledge. Besides tradition (synergetics is not part of a usual university curriculum), the only obstacle to its wide distribution among students may be its fairly high price.

Experienced readers will certainly profit from the variety of examples presented and the rather detailed reference section, a good guide to the topical literature. It is a pity, however, that some of the important work of several Japanese groups on nonlinear chemical reactions is missing—instead, the author has chosen to cite unpublished work carried out by his own group. But this minor weakness is by far outweighed by many advantages.

## Quantum mechanics

*The Uncertainty Principle and the Foundations of Quantum Mechanics. Edited by W. C. Price and S. S. Chissick. Pp. 572. (Wiley-Interscience: London and New York, 1977.) £19.50; \$38.*

BEING a collection of articles, this book cannot be quite faithful to its title: particularly since it is just one book in a series of books, each designed as a tribute to one of the founders of modern physics. Clearly, such publications are not intended to provide anything like a systematic and critical survey of a subject, especially when the latter is highly structured, as is the case with regard to the foundations of a discipline. But what such books can do is to present significant partial results and to direct the reader's attention toward recent specialised research. This is in fact what is achieved, and in a highly satisfactory way, by this book.

Although I benefited from several of the valuable articles the book contains, let me follow my own taste in selecting just one for review: the contribution by G. Lanz. This paper bears on what is often considered to be the only problem remaining in the foundations of quantum mechanics, namely the problem of measurement. Its description of the difficulties besetting that problem is clear. So is its classification of the two conceptions of quantum mechanics that (barring non-local hidden variables) one may still discuss quantum mechanics as the basic theory of physics or quantum mechanics as a mere theory of microsystems, anchored on a (still to be created) theory of macrosystems. The author considers that the first view should be dismissed because of insuperable difficulties with the problem of measurement. As for the second conception, it obviously requires a theory of macrosystems, and an unambiguous definition of what a macrosystem is.

Lanz acknowledges that he has until now no completely definite answers to such questions. He sketches, however (with some profusion of mathematical detail), an approach based on Ludwig's formalism which he believes is promising. It involves a limiting procedure the physical meaning of which is unfortunately not discussed. The general idea is to extract from the N-body theory a part that could be used for a theory of macrosystems; the rest could then be thrown away as physically irrelevant. An interesting but perhaps premature question is whether the future theory will be able to define macrosystems in such a way that at least some finite (and really existing) systems are macroscopic.

## Outlines of Mercury

*The Atlas of Mercury.* By Charles A. Cross and Patrick Moore. Pp. 48. (Mitchell Beazley: London; Crown New York, 1977.) £5.95: \$10.

JUDGING by the presence of the word "telescope" in the glossary at the back of this book, Cross and Moore are attempting a relatively popular treatment of their subject. To this end, in addition to the glossary, they provide helpful diagrams to explain anything that might give pause for thought; for example, why Mercury has a day which is two of its years long. This consideration, shown also in the innumerable illustrations and photographs provided, makes the book easy and informative reading for the relatively uninitiated; whereas, on the other hand, its comprehensive nature should mean that it is not without interest for more advanced readers.

The broad scope of the book also provides a neat way of illustrating just how much of our present knowledge of Mercury we owe to that triumph of American technology, Mariner 10, since the whole history of observation (including much duplication) up to the time of Mariner 10, takes up far less of the book than the results gained from that one space-probe. Those who do not have the time to count the relevant number of pages need only compare Chapman's pre-mission map of the planet (p5) with the map drawn by Cross. It ought perhaps to be remarked, however, that Chapman's map is the upper of the two described on p5 and that it is not the latest pre-Mariner map; this distinction belonging to a map drawn by J. B. Murray *et al.* (*Icarus*, 17, 576-584; 1972). Cross's excellent maps, which form the basis of this book, are centred on the useful subsolar point, and the accompanying photographs give an accurate idea of the planet's surface, perhaps the only omission being a high resolution picture of the Hilly and Lineated Terrain. Also, some mention of the processing these pictures have undergone might have been interesting.

The text accompanying the pictures, however, is the weakest part of the book. There was just not enough geological nitty-gritty to maintain my interest in the endless succession of craters; and calling them circular "enclosures", "formations" or "walled plains" did not help. It could be said that this is the criticism of a geologist, and rather unfair, since the book is an elementary one wherein the authors are clearly trying to keep things simple, but the approach of describing things by quadrants and vast numbers of photographs rather than subjects has provided gaps for the astronomy-orient-

ated authors to stray into, and go astray in, the geological field. For example, on p24, it is argued that, because of the lower number of scarps and the "various younger craters and basins", the area covered by the South-West Quadrant is younger on the whole than the South-East Quadrant. In fact, it is the oldest features which indicate the age of the terrain and in terms of age and distribution of craters, the South-West Quadrant could be older, if anything, than the South-East, but whether it is or not, the statement would have been unnecessary in the first place if something more solid had not been cut out by the simplification process.

A key to the age of the surface is the nature of the Intercrater Plains, which on p18 are correctly described as the regions between the main craters (assuming there is nothing else there, such as Smooth Plains). In the next paragraph, however, it is stated that there is an "obvious" resemblance between this intercrater unit and the highlands of the Moon, which for the most part are nothing but craters. The original description (Trask and Guest, *J. Geophys. Res.*, 80, (17), 2461-2477; 1975) is quite clear: "Intercrater Plains (unit) has a closely similar analog on the Moon in the Pre-Imbrian Plains of Wilhelms and McCauley (*Miscellaneous Geological Investigation Map* 1-703, US Geological Survey; 1971)". That is to say, the Intercrater Plains are similar morphologically to terrain situated between the main craters of a relatively sparsely cratered unit within the southern highlands of the Moon. The lunar unit is of much smaller extent and for this reason, among others, is not thought to originate in the same way.

On p30, a prominent ray is said to be "clearly a northward extension of Heemskerck Rupes". If this is so, then it is an exciting discovery linking what has hitherto been considered as a superficial unit, thrown out by the impact of a meteorite, to a feature interpreted as a very large compressional fault scarp in the planet's crust. I am not excited. On p35 Rupes Zeehan is said to be formed from wall remnants of pre-Caloris craters. Certainly, it seems to be influenced by them, but faces the wrong way for the authors' description to be correct.

On p21, it is indicated that the large scarp in the crater Po Ya "seems to be" a lava front rather than a compressional feature. There are good examples of *small* scarps apparently confined to the Smooth Plains (not present in Po Ya) on some crater floors which some think might be the fronts of highly viscous lava flows (c.f. highly fluid mare basalts). The Po Ya scarp is not one of these. This error is an example of the heavy volcanic bias present in the book. Thus, it is thoroughly misleading of the authors to suggest that there is any controversy over

the cause of the craters on the Moon (and therefore Mercury), even if they do plump for a mixture of both impact and volcanic hypotheses. The vast majority of craters on the Moon, Mars and Mercury were caused by the impact of impinging space debris and because they are morphologically different from the volcanic features also present on the Moon and Mars (but not yet pointed out with any confidence on Mercury), there is no argument as to their origin.

If all this is not entirely compatible with the implication in the proud claim on the cover that this is "the most concise and accurate account of the planet available" (Sir Bernard Lovell), it is also true that, although the mistakes tend to mislead or confuse as to certain pictures or features, they do not seriously misrepresent the fundamental processes which have shaped the planet's surface. In addition, apart from the volcanic bias, the authors do strive throughout to maintain an admirable scientific restraint. For example, the attractive theory that Mercury was once a satellite of Venus is quite properly described as "still highly speculative". On the whole then, this book can be commended to the readers for whom it was written. **W. P. O'Donnell**

*W. P. O'Donnell is a research student in planetology at University College, London, UK.*

## Satellite technology

*The Versatile Satellite.* By Richard W. Porter. Pp. +173 (Oxford University: Oxford and London, 1977.) £4.95.

THE author sets himself the task of explaining "what a satellite is, how it is put into orbit (and why it does not promptly fall down again), what special considerations enter into its design, and especially what it is 'good for' and why". Since all of this is attempted in 173 pages, it is not surprising that the reviewer, an environmental scientist, found the treatment of environmental applications was rather superficial. Nevertheless, a great deal of technical information is conveyed in a clear and concise manner.

The book is well structured, beginning with the history of launching the satellites and their evolution from German and Russian rocketry. This is followed by a useful explanation of orbits and energy requirements for different types of satellite configurations. In a discussion of design requirements, emphasis is placed on the special circumstances of lack of atmosphere, absence of gravity, ionosphere, thermal environment, electromagnetic radiation, geomagnetic field, charged particle environment, and micro-meteoroids. The author praises the satellite designer for overcoming this unfriendly satellite environment within limitations of weight and cost. However, the cost-benefit aspects of the satellite programmes are not discussed in depth in this book.

The environmental scientist should have particular interest in those chapters explaining "what it is good for and why". These discuss applications in the fields of communications; weather forecasting and monitoring; navigation; surveying the oceans and land; monitoring flora, fauna and fish; and spaceborne laboratory experiments.

The impressive growth of satellite communications is well documented and the characteristics of Intelsat satellites are described in some detail. The technologist and engineer may revel in the details of stabilisation, antennas and electronic systems, but all readers will flinch in the face of space jargon — for example, SPADE — "a super-acronym for single channel per carrier pulse code modulation multiple access demand assignment equipment". Even Mr Porter is moved to comment that "the jargon gets worse and worse but really there is no way to avoid it". Although agreeing with this, one wishes a glossary of acronyms had been included so that one does not have to hunt through pages to find the explanation of a particular term.

The section of the book dealing with the surveying of the oceans and the

land gives a good technical description of the "Earth's Resources Technology Satellites. Some of the illustrations used to demonstrate different spectral responses are disappointing, especially Fig. 7.6. Also one notes that the concept of the spectral signature, first mentioned on p98, does not receive further explanation until p127. Likewise, problems affecting the spatial extension of supervised and unsupervised classifications of digital data are not discussed. As a result, the casual reader may be left with the false impression that recognition of crop types is a simple matter.

The informed reader will feel that the present capability of LANDSAT in respect of mapping soils and land use is somewhat overstated. One may note that recent pronouncements by NASA officials are more cautious. For example, J. Morrison, (*NASA Earth Resources Survey Program: Problems and Prospects*, European Space Agency Symposium on Remote Sensing of Earth from Space, Strasbourg, 1977) writes "I do not think we will be able to do this (that is, the Worldwide Crop Information System) successfully until about the 1984 period. The reason is that the present LANDSAT satellites simply do not have the resolution necessary for providing worldwide crop data, particularly in small field situations". Likewise, the assertion that plant disease can often be detected in satellite images before it is apparent to the casual observer on the ground was not borne out by the Corn Blight Watch Experiment (R. B. MacDonald *et al.*, *Results of the 1971 Corn Blight Watch Experiment*, Proc. 8th Int. Symp. Remote Sensing of the Environ-

ment, 1, 157, Ann Arbor, Michigan; 1973). It seems likely that such achievements must await the launch of LANDSAT-D and the Thematic Mapper.

Perhaps the most interesting part of this book is the chapter entitled "Laboratory for Science; An Observatory for Astronomy". This presents the case for space experiments and space observations in a succinct and effective manner. Subsequent sections dealing with the manned satellites and the Shuttle programme are also useful. One feels, however, that the role of the European Space Agency in the Spacelab programme could have been given greater prominence. In contrast to the space race between the US and the Soviet Union, the Spacelab programme provides a welcome example of international collaboration. Further discussion of Spacelab would also have revealed some of the initial limitations of the Shuttle in respect of mission duration and maximum inclination of orbit when launched from the Eastern Test Range.

In the last paragraph, Mr Porter notes that the future depends on the use that is made of satellite technology. It is increasingly apparent that there are considerable problems of technology transfer to be overcome before satellite information will be used to its full potential. This book provides an interesting glimpse of the technologist's world and will help the potential user to understand some of the engineering constraints on satellite systems.

L. F. Curtis

L. F. Curtis is Reader in Geography at the University of Bristol, UK.

## Parasitic Protozoa

*Parasitic Protozoa.* Vol. 4: *Babesia, Theileria, Myxosporidia, Microsporidia, Bartonellaceae, Anaplasmataceae, Ehrlichia, and Pneumocystis.* Edited by J. P. Krier. Pp. xv+386 (Academic: New York and London, 1977.) \$32.50; £23.05.

I HAVE already commented on the fact that the scope of this series encompasses more than the Protozoa (*Nature*, 268, 773; 1977); and favourably, as the treatment of parasitic Protozoa along with other parasitic organisms of similar basic behaviour, multiplying in the vertebrate host, is more likely to be conducive to exchange of fruitful concepts than the traditional association of Protozoa with the helminths, organisms of a basically different mode of life. The present volume is an illustration of this useful format, presenting ten chapters dealing respectively with *Babesia* in domestic animals and in man and other hosts; with *Theileria*, *Myxosporidia*, *Microsporidia*,

*Bartonella* with *Grahamella*, *Anaplasma*, *Aegyptianella*; with *Eperythrozoon* and *Haemobartonella*, *Ehrlichia* and *Pneumocystis*. The volume deals with a range of organisms all of which are important in relation to disease in man or his domestic animals, interpreting the latter so as to include his cultivated fish and insects.

The reviews are excellent up-to-date summaries of their subjects, many of which are diffusely scattered in the literature. They will be popular as systematic first readings or as reference guides to the 'state of play' of their respective subjects. The book is well presented and indexed, with a few line diagrams and half-tones; the last do not receive special treatment as regards the paper on which they are printed and so are adequate rather than excellent.

## Another nuclear option

THE world will need a new source of energy when the oil and gas runs out: on that most are agreed, from the Friends of the Earth to the toughest champions of the nuclear industry. But how much energy? By when? And from what source? These are highly political questions, but they involve a technical one: what sources of energy are there? This question in turn, however, is not entirely apolitical. The gigantic momentum of the nuclear industry, set up to tame the atom bomb and, no doubt, to salve the consciences of the physicists ("We have known sin," said Oppenheimer, after Hiroshima), has determined the principal option: the fission of uranium nuclei. There has been too little cash for options other than nuclear and too little work on them. One thinks first of such fashionable renewable resources as wind, wave, sun, and geothermal energy. But, it turns out, it is not only renewable resources that are under-researched. There are specifically nuclear options that have passed almost unnoticed—as our feature this week shows (page 376).

The nuclear industry cannot continue indefinitely with existing reactors, for they consume only a tiny part of natural uranium—the fissile isotope  $^{235}\text{U}$ . The bulk of the uranium, consisting of stable  $^{238}\text{U}$ , is "wasted". This was clear at the beginning of the nuclear power programme, so it was natural to develop a system which would burn the  $^{238}\text{U}$ . This was the fast breeder, which lets the chain reaction in the  $^{235}\text{U}$  go so fast that some of the released neutrons convert the  $^{238}\text{U}$  to fissile plutonium,  $^{239}\text{Pu}$ . The plutonium they "bred" can in turn chain-react to produce energy. This system is not only economical in uranium—it seems on the face of it to be necessary in a principally uranium-based economy, for the energy-equivalent reserves of  $^{235}\text{U}$  that are extractable with a net yield of energy amount to only one-fifth of the oil reserves. Hence the dash of the nuclear industry towards the fast breeder reactor.

Yet there is an alternative to the fast breeder which will still conserve uranium—the thorium-uranium cycle. Perhaps it was the military need for plutonium; perhaps it was the simple logic of reaching towards the untapped 99% of uranium, the teasing  $^{238}\text{U}$  nucleus, that concentrated all attention on the fast breeder. But the Th-U cycle, which, at least according to its growing band of advocates, avoids the tremendous power density of the fast breeder core ( $\frac{1}{2}$  MW per litre, compared with 3 to 100 kW per litre for a thermal reactor), which reduces the problem of the long-lived wastes like americium and curium, which protects against

illegal diversion of fuel (it becomes highly radioactive), and which with proton accelerators to "top-up" the fissile content of the fuel rods might even avoid reprocessing altogether, has been looked at hardly at all outside some work in Canada and the US.

Pressure to work on the cycle comes from those resisting the fast breeder, and also from an unexpected source—accelerator physicists. The latter are to be distinguished from the high energy physicists who merely use accelerators. In a time of declining budgets for high energy physics the accelerator physicists are looking for someone else to sell their accelerators to; and the energy business seems a good bet. Yet they should not be dismissed for their self-interest; they are ingenious people and their proposals should be looked at carefully. Already they have initiated what may be the fastest route to fusion power (ion beam fusion). In the Th-U cycle they are offering ways of improving the efficiency of the cycle beyond what seems possible in the Canadian CANDU reactors until the cycle reaches true breeding—the creation of more fissile nuclei, from a non-fissile source, than are consumed in the reactor. It seems impossible to consider the Th-U cycle without considering the contribution the accelerator physicists can make.

Once breeding has been established in the Th-U cycle the reserves of thorium, not uranium, are the ultimate constraint. There seems to be plenty of thorium about, with major reserves in Canada, India, and the USSR. There is probably quite enough extractable with sufficient energy economy to exceed the energy reserves of the fast breeder fuelled on uranium.

Leaving aside the vexed arguments about whether we need a nuclear power source anyway, whether it is even economic, and whether its capital intensity is appropriate for the Third World (which is potentially the world's major energy consumer), it would seem at least that the thorium-uranium cycle, with accelerator back-up, should be given very serious attention as part of the political energy equation. It may be, of course, that it is too late; that we will need our new sources of energy before Th-U can be developed into a commercial proposition. Or that the philosophically and—if you are of a certain leaning—politically attractive renewable resources, together with energy conservation and coal, will become practical and economic alternatives before you can say "fast breeder". In fact, given the opposition to the latter, Th-U plus accelerators may be the nuclear industry's last chance. □

# Conserving uranium without the fast breeder

The fast breeder, with all its dangers, is not the only way forward for the nuclear power programme. **John Davies** explains

NATURAL uranium, unaugmented by breeding, will provide a relatively small reserve of energy: uranium energy reserves amount to only one-fifth those of oil. The best-promoted nuclear solutions to this problem are the fast breeder reactor (FBR) and controlled fusion. The former is a means of stretching the uranium resources by two orders of magnitude; the latter promises virtually unlimited power from sea-water. Neither method is straightforward, although both were being discussed in undergraduate lectures twenty years ago. A commercial FBR is not yet operational and the design of a fusion reactor providing energy break-even is still in the unplanned future. Moreover FBRs, with their use of plutonium, are responsible for many of the strong, reasoned objections to nuclear power. However, few have realised that there are several other ways of breeding fissile materials that avoid fast reactors and their problems.

Breeding—creating fissile from non-fissile material—requires an intense source of neutrons. Neutrons can be produced by an FBR; or by a fusion reactor (yet to be built); or by using proton accelerators. The last option has not been widely discussed.

To make the arguments clear, I shall first describe some of the basic physics occurring in reactors, particularly to explain what "breeding" is and why it is essential. I shall then look at the objections to FBRs before examining the alternative means of breeding to demonstrate a system that I believe is practical, economically viable, and safe.

As medium-weight nuclei are the most stable, considerable amounts of energy are generated either when two light nuclei fuse together, or when a heavy nucleus splits into two smaller ones (undergoes fission). To exploit either possibility requires an energy barrier to be overcome. (If there were no energy barrier all light or heavy nuclei would by now have fused or fissioned leaving only medium-weight nuclei.) Another requirement (in fission) is a mechanism for maintaining a chain reaction—where the fission of one nucleus in turn induces the fission of others.

In fission, the energy barrier is, roughly speaking, the surface tension of the nuclear droplet. A heavy nucleus approaching fission becomes progress-

ively distorted, and the energy of the increased surface provides the fission barrier (small droplets of water are stable for the same reason). The impact and interaction of a neutron of the right energy overcomes this energy barrier. If, in turn, each resulting fission releases more neutrons (as it will, as heavy nuclei are neutron-rich) the neutrons will maintain a chain reaction with an unending succession of nuclei being induced to split.

Let us now consider fission in more detail. Thermal reactors use the fissile nuclei  $^{235}\text{U}$ ,  $^{239}\text{U}$  and  $^{239}\text{Pu}$  where the binding energy provided by the capture of a thermal neutron is sufficient to overcome the surface energy barrier against prompt fission of the resulting  $^{234}\text{U}$ ,  $^{236}\text{U}$  and  $^{240}\text{Pu}$ . Each induced fission also provides several neutrons which can then start a chain reaction. But the trouble is that the isotopes  $^{235}\text{U}$  and  $^{239}\text{Pu}$  are artificial; and  $^{238}\text{U}$  is a rare isotope of uranium, the most abundant being  $^{238}\text{U}$ .

Unfortunately, the abundant  $^{238}\text{U}$  will not do for fission, as the figure shows. This plots the effective number of neutrons per fission ( $\eta$ ) against the kinetic energy of the captured neutron; and shows the fission neutron energy spectra in thermal and fast reactors. In contrast with (say)  $^{235}\text{U}$ , the last, odd neutron in  $^{238}\text{U}$  has a smaller binding energy. Consequently only the most energetic neutron coming from fission can cause further fission by capture in  $^{238}\text{U}$  and so  $^{238}\text{U}$  cannot maintain a chain reaction.

With thermal reactors only, using natural uranium, uranium resources are insufficient to maintain a long-term nuclear energy programme. The only naturally occurring fissile isotope is  $^{235}\text{U}$ , present at 1 part in 140 of  $^{238}\text{U}$ . Moreover it is only part-burnt in thermal reactors. This leads to the idea of trying to "breed" fissile isotopes, by using the excess neutrons in the chain reaction to create fissile nuclei in otherwise non-fissile elements.

From each fission of  $^{239}\text{U}$  one neutron is required to maintain the chain reaction and 0.2 neutrons escape. Any excess over 1.2 neutrons could be used to convert  $^{238}\text{U}$  or  $^{232}\text{Th}$  to fissile  $^{239}\text{Pu}$  or  $^{233}\text{U}$  via

(Here the notation  $A(n, \gamma)B$  means nucleus A absorbs an incoming neutron and becomes nucleus B, emitting a gamma ray (a photon) in the process.

The notation  $B \xrightarrow{\beta^-} C$  means B decays by  $\beta^-$  emission to C with a half-life of  $x$  minutes.)

The difference between the two reactions is that the first needs fast neutrons, while the second can use slow ones. The reaction  $^{238}\text{U} \rightarrow ^{239}\text{Pu}$  occurs to a small extent in present thermal reactors (in so far as there are a few fast neutrons around) and chemical processing can enable up to 1% of all available uranium to be burnt. Even so there is probably little point in planning further thermal reactors (as there will be insufficient uranium to fuel them and existing reactors).

## Breeding in a fertile blanket

The fissile material for reactor fuel can be produced from fertile material using the excess neutrons from a reactor and the above reactions. In practice this could be done by surrounding the reactor with a 'blanket' of fertile material where the spare neutron would then 'breed' new fuel. In fact if  $\eta \geq 2.2$ , with one more neutron per fission than required to maintain the chain reaction, then breeding in a fertile blanket will maintain or increase the fissile content and allow almost all the uranium to be burnt. The figure shows that a fast reactor burning  $^{239}\text{Pu}$  surrounded by a fertile  $^{238}\text{U}$  blanket absorbing the excess fast neutrons is the best bet.

Is this really true? Much of the reasoned objections to nuclear power are consequent on the following problems of the fast breeder reactor:

- New technology—breeding around a 500 MW dustbin whose reactivity—burning rate—can be accidentally increased in micro-seconds; no artificial control is fast enough.

- Time—whether thermal reactors can produce enough  $^{239}\text{Pu}$  to fire a FBR regime whose time to breed the initial fissile content is anyway commensurate with their working life.

- The expensive, messy and dangerous chemical separation of fissile materials, in particular  $^{239}\text{Pu}$ , from spent fuel elements. This separation greatly increases the possibility of

- $^{239}\text{Pu}$  being diverted into nuclear weapons; this is further exacerbated by the considerable transporting of fissile material and by inaccuracies of assay of  $^{239}\text{Pu}$ , which can be so large as to be greater than the amounts needed for

many bombs. (This is called the "Muf"—materials unaccounted for—problem.)

● The cost—as yet not evaluated—capital, running and political—especially for trying to make them safe.

Thermal reactors on the other hand involve established technology. The figure shows that such a reactor fuelled with  $^{233}\text{U}$  has a breeding gain ( $\eta-2.2$ ) greater than 1.00 i.e., as much  $^{233}\text{U}$  will be created in a  $^{232}\text{Th}$  blanket (absorbing the slow neutrons) as is burnt as fuel. Unlike  $^{239}\text{Pu}$ ,  $^{233}\text{U}$  is automatically safeguarded against illegal diversion into bomb-making by the intense  $\gamma$ -rays coming from the simultaneously produced  $^{232}\text{U}$ ; additionally one can add sufficient  $^{238}\text{U}$  to make life difficult for the bomb maker but still keeping the  $^{233}\text{U}$  fissile. Such reactors avoid plutonium and the technological problems of FBRs. Also they ease the waste problem: the proportion of difficult transuranic elements (which take a long time to decay) is considerably reduced.

Thermal reactors fuelled on  $^{233}\text{U}$  can have a breeding gain of 1.00 or greater in a Th blanket. But considerable development would be necessary to make this economic. Additionally chemical re-processing of the spent fuel rods, as yet undeveloped, may be necessary.

Consider what a well established, practical and economic reactor can do with a Th-U cycle. The Canadian Deuterium Uranium (CANDU) series of heavy water moderated thermal reactors have high neutron economy and use natural uranium so there is no chemical separation. They can operate on a Th-U cycle with breeding gain as large as 0.92. Thus to use all the available thorium requires only 8% of the  $^{232}\text{Th}$  atoms to be converted to  $^{233}\text{U}$  by non-nuclear means.

Some fusion enthusiasts are lowering their expensive sights, ignoring energy output and promoting fusion reactors as intense neutron sources for fertile to fission conversion. This is not surprising! Fusion reactor design is replete with problems such that only a 2000 MW TOKAMAK has promise of creating as much energy as it consumes even with the most easily ignited  $\text{D}(\text{T}, \text{n})$   $^4\text{He}$  reaction. It is possible that the 14 MeV neutron is far more valuable for breeding than for heating, each neutron converting two or more fertile atoms into fissile ones. Even so despite the relaxed conditions for only providing neutrons fusion technology is still a dream and many regard a hybrid arrangement as combining the worst features of fission and fusion.

### Proton accelerators

Of all the big advanced technologies, that of accelerator building can claim to have established the most consistent

track record. The high intensity accelerator at Los Alamos is well on the way to its design beam current, the CERN SPS is working ahead of schedule within its design budget while the high energy accelerator at the Fermi Laboratory is already  $2\frac{1}{2}$  times its original design energy. At several laboratories high intensity accelerators are now replacing fission reactors as research instruments providing high intensity neutrons.

The intense neutron fluxes from such particle accelerators can effect fertile-to-fissile conversion and so produce far more energy than they consume. A 1 GeV proton interacting in a uranium target produces 60 low energy neutrons by a process known as spallation; each neutron can change one  $^{232}\text{Th}$  atom into one  $^{233}\text{U}$  atom in a fertile thorium blanket surrounding the uranium target; each  $^{233}\text{U}$  atom can fission in a CANDU reactor producing 200 MeV of available kinetic energy; of every 100  $^{233}\text{U}$  atoms so burnt, 92 will have been produced in a thorium blanket around the same or similar reactor while only 8 will have had to be produced via an accelerator. So effectively a single 1000 MeV proton produces

$$100 \times \frac{60}{8} \times 200 = 150,000 \text{ MeV}$$

This is possibly a lower estimate as there may be neutron multiplication in the blanket.

Accelerators are inherently cheaper to build than reactors and a large proportion of the accelerator operating power could be provided from heat generated in the target. The accelerator design criteria are high efficiency of radio-frequency power to beam energy conversion, minimal power usage in other parts of the accelerator (such as magnets) and high extraction efficiency.

The ratio of neutrons emitted to neutrons absorbed, in collisions between neutrons and nuclei, plotted against neutron energy. Also shown are the neutron spectra from fission directly (dotted line) and in a thermal and fast breeder reactor

Most work on meeting these requirements has involved a high intensity, medium energy, linear accelerator which is essentially an extension of the 800 MeV Los Alamos machine, now being worked up to 1 mA beam current. However, as a good example of lateral thinking, is a suggestion that these requirements can also be met by a low current, very high energy accelerator, an extension of the 400 GeV CERN SPS or the 500 GeV accelerator at the Fermilab.

A Canadian group including Fraser, Hoffman and Tunnicliffe at Chalk River are designing a 100–300 mA, 1 GeV proton linear accelerator that would breed enough fuel to supply the 8% deficiencies of a dozen, 1,000 MW CANDU reactors operating on a uranium–thorium cycle. The fertile blanket would consist of new fuel pins that would subsequently go directly to the reactor after a pause to allow for  $^{233}\text{Pa}$  decay. A sophisticated fuel management scheme is conceivable in which partially-burned fuel pins are upgraded by re-insertion in the target and then returned to the reactor.

Another suggestion, from Wilson at Fermilab, is for a superconducting 1000 GeV accelerator with an intensity of  $1-2 \times 10^{13}$  protons per second. At this energy the number of spallation neutrons is still increasing linearly with energy and so a single proton will produce 60,000 neutrons in a block of uranium. High energies and low currents mean low beam loss and efficient conversion of radio-frequency power to beam energy for protons travelling close to the velocity of light. Fermilab's superconducting energy doubler will provide 1,000 GeV protons. The intensity required for energy break-even must be increased from the present  $10^{12}$  protons per pulse by an amount that one has come to expect over an accelerator's life-time. This

neglects the effective  $\times \frac{100}{8}$  energy

multiplication obtained by breeding  $^{233}\text{U}$  for CANDU reactors.

Accelerator spallation neutron sources are being built at several laboratories as research instruments to replace fission reactors as a source of high intensity neutrons. Accelerator scientists regard upgrading spallation sources for breeding purposes as a reasonable extrapolation of existing, successful techniques. This would make the thorium–uranium cycle in thermal reactors a serious contender as a nuclear fuel source with the added bonus (to many the over-riding attraction) that objectionable material need never be removed from the fuel rods. □

## The Ganges shared out

BANGLADESH and India have agreed to share the water from the Ganges and to increase the river's flow. The interim agreement lasting five years, which the two countries signed on 5 November, states that they will share the water during the dry months from 1 January to 31 May. Estimates of the amount of water available are based on the recorded flow of the Ganges at Farakka from 1948 to 1973. The water will be released to Bangladesh for ten days at a time in three instalments each month from January to May.

The agreement also provides for water sharing during the driest period from 21 April to 30 April. At that time, water sharing between India and Bangladesh will be at the rate of 20,500 cubic feet per second and 34,500 cubic feet per second respectively. The total flow at Farakka during the period averages 55,000 cubic feet per second. The actual availability above or below the amount calculated for the period will be shared between the two countries in the same proportion. The signing of the agreement marks the culmination of protracted negotiation between the two countries which has lasted for 25 years and it is thought to be unique between riparian states.

The agreement was signed at about the same time as the Second Committee of the United Nations Environmental Programme (UNEP) constituted an intergovernmental group of experts to draft guidelines for sharing natural resources harmoniously between states. A Bangladesh representative has proposed that a conference on international rivers be organised to evolve and strengthen an institutional framework on a national, regional and international basis to deal with the problems of exploiting and developing international rivers. It is

also suggested that UNEP should be responsible for advising on the development and non-wasteful use of national resources based on sound environmental policy.

The importance of the Ganges to Bangladesh can be judged from the fact that the Ganges delta covers about 37% of the total area of Bangladesh, and contains about one-third of the total population of the country. The river provides water for drinking and other domestic and industrial uses, sustains agriculture, forestry and fisheries, and facilitates in-land navigation. The increasing demand for greater agricultural output means that water is needed throughout the year. The water available during the dry months may not be enough for the four thousand acres of paddy land dependent on the Ganges.

The task of feeding the fast growing

population of Bangladesh from the limited land and water resources is a challenging problem. Cultivating rice, the staple food of the people, is confronted with two serious handicaps—the excess of water during the monsoon and its scarcity throughout the dry months. Controlled irrigation is an alternative but expensive proposition. The Bangladesh Planning Commission, in consultation with the Water Resources Division and the Water Development Board, has proposed four pilot projects, for four different zones of the country, to develop a way of conserving water during the wet season and making it available to the farmers for the rest of the year, particularly during the lean months. The water conservancy programme will also provide a suitable environment for pisciculture and other aquatic sources of food.

## UK Energy Commission meets

THE DESIRE of Mr Tony Benn, Britain's Secretary of State for Energy, to see a fully-integrated national energy policy came a step nearer to fruition on Monday with the first meeting in London of the newly-established Energy Commission.

The commission is an advisory body set up earlier this year to provide a regular forum for representatives of both the producers and consumers of energy, to discuss long-term strategy and specific problems.

Mr Benn, speaking after Monday's meeting, said that he was aware that the Energy Commission did not represent as powerful a set of voices on

alternative as on traditional sources of energy—at least as far as research and development was concerned.

"The Government has been criticised by Sir Brian Flowers, as chairman of the Royal Commission on Environmental Pollution, and others for not paying enough attention to alternative sources of energy, and this is a criticism which we accept," he said.

One of the first requests which he had made to Sir Hermann Bondi, recently appointed chief scientist at the Department of Energy, was to look at the balance of research effort and investment between conventional and more novel forms of energy produc-

tion.

A great advantage of research in this area was that it was relatively cheap, at least in comparison with the capital intensive investment stages. "It would be sensible for us to expand our support for research over a wide range of possibilities, and then let the development stage bid for part of the energy budget. This is an area in which I am convinced that, given the determination, we can make more efforts more quickly."

The 24-members of the commission include representatives of the energy-producing industries, relevant trade unions, various employers' organisations and consumer bodies. It has been created by Mr Benn following last year's National Energy Conference, at

which the issue of energy policy was for the first time in Britain officially pushed into the arena of public debate.

According to its terms of reference, which were announced by Mr Benn in July, the commission will be concerned with two main issues: the developments of a strategy for the energy sector in the United Kingdom, and specific aspects of energy policy that arise from time to time.

On both of these, according to Mr Benn, the commission will "seek to form an agreed view", feeding into the process by which he hopes that the Government will eventually be able to publish annual reports on the energy situation. These would contain reviews of decisions taken, current prospects, and matters likely to come up for discussion.

As a first step, the Government is expected to publish a Green Paper on energy policy in Britain early in the new year. This will be based on a working document on energy policy which was prepared for the Energy Commission, and published by the Department of Energy last month.

The working document, which was welcomed by environmentalists as indicating slightly more tentative attitude

towards energy issues than previous government statements, and reduced by 10 per cent an earlier forecast of energy needs in the UK by the year 2,000, was one of the main items on the agenda of Monday's meeting.

Among the comments made, for example, was that little attention had been given to the problem of the availability of skilled manpower for the energy industries, a point which Mr Benn said would, like others made at the meeting, be taken into account in the drafting of the Green Paper.

Mr Benn expressed satisfaction, however, that in line with what he calls a "consensus approach to energy policy", the members of the commission had given general support for the working document which was to form the basis of the Green Paper. "We have hit on an energy programme for December 1977 which can claim a wide measure of public consent and understanding", he said.

He emphasised, however, that the commission was purely advisory. Although it provided a chance for the various power industries to compare notes on their future programmes, there was no suggestion that the commission should take over either the

responsibilities of the fuel industries, or those of the established Parliamentary and Governmental channels.

It remains to be seen whether this will be sufficient to maintain the confidence both of the nationalised industries, with their recently-expressed concerns about government "interference", or the trade union representatives, who would like a body such as the commission to assume a great executive responsibility.

Earlier this year Mr Frank Chapple, general secretary of the Electrical, Electronic, Telecommunication and Plumbing Union, and chairman of the TUC's Fuel and Power Industries Committee, six of whose members represent the trade union interest on the commission, suggested that there was a need for a body such as the commission to "bang heads together and work out mutually agreed policies".

Mr Chapple warned: "We are not prepared to rescue the formulation of energy policy from the short-term vagaries of the market-place only to see it taken over by bureaucrats in Whitehall and removed from the public domain."

David Dickson

## A second bang in the Urals

THE Kyshtym event of 1958 in many ways parallels the Tungus event of 1908. Both took place in darkest Russia. Both attracted virtually no outside attention for almost two decades. And both, once publicised, became the subject of much speculation, both informed and uninformed, with every new piece of evidence only adding to the mystery.

One of the few clear pieces of evidence to what happened at Kyshtym is given by Dr Lev Tumerman, now of the Weizmann Institute. He visited the area in 1961 and reports extensive devastation, typical of a nuclear disaster. Dr Tumerman, however, will not commit himself on the cause, stating only that it could not have been an accident in an operational power station, since at that time the Soviet Union possessed no such installation. Even in 1961, the first such station, at Beloyarsk, was still in the foundation-laying and concrete mixing stage.

Dr Zhores Medvedev, who visited the area at much the same time, is convinced that the explosion occurred in a nuclear waste store. Although the storage of waste products involves a real leakage hazard, it is difficult to see how it could cause an explosion. One Russian scientist (not a nuclear physicist), told *Nature* that he himself felt that Medvedev's explanation was quite possible, since the Soviet regime pro-

duces in its scientists an "attitude of neglect", so that proper precautions are everywhere ignored. This explanation would, however, apply equally to an explosion at a prototype reactor plant, as much as at a waste dump.

The latest step in the enigma is posed by the release of hitherto secret documents by the CIA. Fourteen documents were released; another 15 exist but are still considered too sensitive, so that, as seems typical for Kyshtym, only partial evidence is available. The involvement of the CIA itself raises a number of questions; in particular, was the notorious U-2 flight over the area

simply part of a routine Union-wide patrol, or was the unfortunate Gary Powers sent to confirm reports already received from a ground-level contact?

Much more mysterious is the fact that the CIA material mentions *two* explosions, one in 1958 and one in 1959. It seems on the face of it unlikely that two nuclear accidents could occur in successive years—even if we admit that an atmosphere of neglect makes Soviet installations peculiarly accident-prone, the fall-out from the first disaster would have surely led to the abandonment of the area, with the shut-down of any project already operating.

Vera Rich

## Was Tungus an astronaut?

SINCE the first expedition, just 50 years ago, to the site of the "Tungus event" of 1908, the explosion has posed a major riddle to geophysicists. The latest in a long line of theories, that of a certain Aleksei Zolotov, poses a further mystery—how, in the conditions prevailing in Soviet science, did it ever get published?

It is well-known that the publication of scientific articles in the Soviet Union is subject to strict controls. No paper may be submitted without a special certificate from the author's place of employment—a regulation which, it would appear, leaves no outlet for either the gifted amateur or the harm-

less crank. When Soviet science has, on occasion, followed its own course, unacknowledged by the outside world, this has been due to either the party bypassing normal academic procedures—as in the case of Lysenko—or else to the initiative of the topmost echelons of the scientific establishment—as with the blanket denial of ocean-floor spreading, or Snezhnevskii's theory of "creeping schizophrenia".

Recently, however, Moscow radio broadcast in both Russian and English a "new explanation" of the Tungus "enigma". The theory itself is not new to Western readers of fringe publications: the devastation, it is claimed,

was due to the explosion of an artificial "alien body", and involved nuclear reactions. Within the apparently monolithic structure of Soviet scientific publishing, its appearance, however, is startling.

There have been a number of expeditions to the Tungus area in recent years. Detailed analyses of soil and peat samples have been made, revealing, *inter alia*, a large quantity of silicate particles (diameter less than 200  $\mu\text{m}$ ) in the 1908 peat layers near the epicentre. Last March, Professor Emlen V. Subbotovich, the geophysicist, announced the findings of these expeditions: all previous theories, he said, including anti-matter, meteorite, or alien spacecraft, were wrong. The explosion was caused by a comet-like body, with density not greater than 0.9  $\text{g cm}^{-3}$ . His pronouncement was made with all the concomitants of a definitive pronouncement. Where, then

does Zolotov's theory fit in?

Last week, a former member of several Tungus expeditions visited London—Dr Khronid Lyubarskii, who was recently exiled for his part in the dissident human-rights campaign. Dr Lyubarskii, an astrophysicist specialising in the physics of meteors and meteorites, fully endorsed the official view that a comet was responsible for the Tungus event. According to him, Zolotov, who was described in the broadcast as a mathematician and physicist, was originally an engineer from an oil prospecting team. How he first became involved with Tungus is not clear; the impression which Dr Lyubarskii gave of him is, however, a familiar one—the self-appointed "expert" who in his own opinion knows far more than the scientist in the field. Zolotov's article, it turns out, did not appear in any scientific journal; hence no "certificate" was needed. It was

published in the monthly *Turist*—perhaps in the hope of attracting holiday-makers into the further reaches of Siberia. And for popular journals, explained Dr Lyubarskii, while there is strict political censorship, there is no control of "scientific" (or pseudo-scientific) content.

It is perhaps inevitable that genuine scientific research is surrounded by a penumbra of more or less wild speculation; indeed, this may be a necessary factor in the growth of science. One of the dangers of a monolithic state-controlled scientific establishment is that the rigid structure of the system can exclude the brilliant amateur, and also the scientist trained in one discipline, who, like Pasteur, does his most significant work in another. However wild Zolotov's theory, the fact that it can still find an official outlet in the Soviet Union is a happy omen.

Vera Rich

FOR years, many adult middle-class males have tried to substitute diet for exercise in warding off heart attacks. The research effort on this "diet-and-heart" question, says George Mann, "has ended in disarray." Dr Mann's conclusions were noted in *Nature* (3 November, page 2) by Dr Rivers.

The popular dogma, which dates from around 1950, has said that diets low in saturated fats and cholesterol, but containing polyunsaturated fats (PUFAs), will produce lower blood-cholesterol levels and will lessen the risk of coronary heart disease. The idea was well-accepted; it was supported by many prominent clinicians and nutritionists. Sales of vegetable oils grew apace, especially those oils for which a slightly higher-than-average content of esters of essential PUFAs could be claimed. Big fields of thistle-like safflowers yellowed the landscape with their blossoms. Safflower seeds furnished the *cordon bleu* of vegetable oils, so rich in PUFAs that you could just feel it doing you good. The oil was hydrogenated to make margarine, even though, as George Mann points out, the hydrogenated, and hence trans, fatty acids have a hypercholesteremic effect. Butter, cream and eggs were to be shunned.

What was the effect of 25 years of these measures? By 1977, as Dr Mann points out, the results show that "a huge cohort of persons past middle age has been recruited to a futile regimen of dietary restrictions". No diet therapy has been shown effective for the prevention or treatment of coronary heart disease. Two of five dietary regimes in which vegetable

oils were featured showed an increased incidence of deaths from cancer in the treated groups.

This may be meaningless, but several experiments have shown an increase in tumour incidence in rats on diets high in polyunsaturated fats,

## Sursum corda

THOMAS H. JUKES

such as sunflower-seed oil and corn oil, as compared with saturated fats.

The vegetable oil motif was for many years the official guide to cooking and eating. Who would dare to challenge the sonorous pronouncements of medical authorities when the punishment for such heresy was incapacitation or death? We could almost feel the waxy cholesterol and tallowy fats clinging to our arterial walls after we suicidally wolfed down scrambled eggs or lamb chops. Thoughtful, health-oriented advertise-

ments gave us tasty recipes, made with vegetable oils. Sugar was added to the list of culprits; it could allegedly give rise to "hard fats" when metabolised. In any case, sugar is sweet, and therefore, sinful.

A new ascetism burgeoned and, true to type, its main objective is restoring sybaritic evil-doers to the path of dietary righteousness. Its leader is Senator George McGovern, whose committee on 'Nutrition and human needs' has issued a preposterous report on 'Dietary goals' which calls for governmental action to implement the prejudices of its writers.

The report says, among other things, that it is necessary [*sic*] to make partial substitution of polyunsaturated fat for saturated fat. Why? What about the rats with cancer? The report quotes the *New York Times* to support its thesis for reducing sugar consumption by about 40%, and speaks ominously of cola-guzzling youngsters (the little devils!) and the need for protection against "hidden sugar". Martini-guzzling adults get off without reprimand or umbrage, but we are told that monosodium glutamate "may be associated with headaches, flushes in the head and body and tingling in the spine". Since most common vegetable food proteins contain 20% or more of glutamate, there should be much tingling after a meal, and don't blame the martinis.

Avast to McGovern and his anonymous bluenoses! 'Tis the season to be jolly! I don't think they know what they're talking about, anyway, even if they have wangled a multi-million dollar appropriation to brainwash the public.

## In support of catastrophe theory

On 27 October we published an article by R. S. Zahler and H. J. Sussmann (page 759) critical of 'incorrect reasoning, far-fetched assumptions, erroneous consequences and exaggerated claims' in biological and social-science applications of catastrophe theory. Here is a selection of responses to the article

SIR,—Zahler and Sussmann have a basic misunderstanding of catastrophe theory: in their criticism they ignore the fundamental concept of stability. Stability lies at the root of the modern mathematical theories of dynamical systems and singularities, of which catastrophe theory is a part. The concept was introduced by Andronov and Pontryagin in 1937, and it has been greatly developed not only by Thom but also by the Russian school, notably Anosov and Arnol'd, and the American school, notably Whitney, Smale and Mather.

The importance of stability in modelling lies in the fact that if a stable model is perturbed, then its qualitative properties are preserved. Thom acknowledges the mathematical and scientific importance of stability by incorporating it into the title of his book *Structural stability and morphogenesis*, in which he first introduced catastrophe theory. On page 762 of their article Zahler and Sussmann ask the rhetorical question: "So we must ask again: what is special about a model that looks like a cusp?" and the simple answer to their question is that the cusp catastrophe is stable, whereas their figure 4 is not.

For details of their criticism Zahler and Sussmann refer the reader to a longer paper of theirs, which is not yet published. However, in the preprint of this paper, which they have circulated widely, there are major mathematical mistakes underlying their main criticisms: I explained some of these mistakes at length to Sussmann when he visited Warwick University in July this year.

Most of Zahler and Sussmann's scientific criticisms are based on misquotations, misunderstandings, misrepresentations, or quotations out of context. I give a typical example. On page 762 under the heading of 'Careless discussion of evidence' they state a number of so-called "facts", including: "Zeeman's embryology paper (*Lectures on Maths in the Life Sciences* 7, 69 (1974)),

besides being mathematically wrong, betrays the author's inexperience in embryology. For example (p. 27), Zeeman likens the embryonic neural tube to a roll of stiff paper which tries to maintain its curl. But experiment shows that cut neural tube persistently tries to unroll".

In these two sentences Zahler and Sussmann manage to misquote both Crelin and myself. Far from contradicting the metaphor, Crelin's experimental work supports it: Crelin writes (*J. exp. Zool.* **120**, 561 (1952)). "The grafts of all the embryos in the rotation series showed a tendency to curl in a matter of seconds after they were severed from the brain. Therefore, if the rotation of the tectum were delayed for some reason such as the graft sticking to the forceps, the graft would curl into the shape of a ball, making it impossible to continue the operation". On page 577 figure 19, Crelin shows a photograph of the graft curled into a ball. Meanwhile on page 127 of my paper (there is no page 27) it is the underlying mesoderm, not the neural tube, that I liken to a roll of stiff paper. The burden of my discussion on that and the preceding pages concerns the forces exerted, *in vivo*, by the underlying mesoderm upon the overlying ectoderm and neural plate, before the latter has rolled up into neural tube, and at a much earlier embryonic stage than Crelin's experiment.

I now give an example of misrepresentation. When sophisticated mathematics is applied to science it is common practice to publish separately both rigorous mathematical proofs and more simplified expositions of the same material: the latter are essential if the work is to be made available to those scientists who are not expert mathematicians. A case in point is my treatment of primary and secondary waves in developmental biology. My initial simplified version, addressed primarily to biologists, is in *Lectures on Maths in the Life Sciences*, while mathematical discussions and rigorous proofs, addressed primarily to mathematicians, are in *Proc. Int. Cong. Math., Vancouver* **2**, 533 (1974) and Wasserman, G. *Acta Math.* **135**, 57 (1975). The mathematical treatment uses stability with respect to a symmetry-group that is appropriate to developmental biology, namely an extension of the group of diffeomorphisms of space-time preserving the foliation by time-paths. Zahler

and Sussmann criticise the simplified version for mathematical naïvety, without acknowledging the existence of the sophisticated version, although the latter has been brought to their attention long ago.

These are two examples: I could point to a hundred others. I have always found that my work has benefited from the constructive criticism of my fellow mathematicians and scientists. However, to argue in print against the determined misrepresentations of Zahler and Sussmann is both tedious for the reader and unproductive, and an adequate answer to this type of criticism is provided by my original papers *Catastrophe theory, Selected papers 1972–1977*. Nevertheless I am prompted to reply to this particular article for three reasons: firstly, their disgraceful omission of any reference to the work of Thom on biology, secondly, their implied dismissal of the fine work of Berry in physics, and thirdly, the potential harm that their article might cause to the work and the careers of other scientists who are using catastrophe theory, particularly the younger ones who have not yet established their reputations.

E. C. ZEEMAN

University of Warwick, UK

SIR,—In response to the criticisms of R. S. Zahler and H. J. Sussmann we wish to point out that contrary to misleading statements they make such as "catastrophe theory is a blind alley", several examples of genuine applications of catastrophe theory already exist in the physical sciences.

For example one of us recently studied the topological behaviour of stagnation points in two dimensional flows where, with the aid of Thom's elementary classification of degenerate critical points, a physical understanding was obtained of the complex behaviour of degenerate and non-degenerate stagnation (critical) points in a particular flow (Berry, M., & Mackley, M. R. *Phil. Trans. Roy. Soc.* **287**, 1–16 (1977)). Further physical applications amenable to direct experimental test exist, some of which were discussed at the Institute of Mathematics and its Applications meeting held at University College London in May 1977.

Concerning the application of catastrophe theory to biology, we agree that some inaccurate or premature claims have been made. In particular, Zeeman's argument for the existence

of primary and secondary waves in developing embryos does not have the logical status of a proved theorem since he has not as yet published the full mathematical proof. Rather, his use of catastrophe theory in a description of differentiation gives rise to the hypothesis that such waves occur and, with the additional postulate of a temporal periodicity of state in the tissue, this application suggests how spatially periodic structures such as somites may arise.

These hypotheses have stimulated experimental investigation, which is a major purpose of model-building. Furthermore, Zeeman's treatment of differentiation has the additional virtue of providing a unitary field description of a process which is often erroneously and misleadingly described in terms of separate spatial and temporal mechanisms. In a subject such as developmental biology, which has barely begun to come to grips with its central problem of morphogenesis in terms of models, it is more important to get the correct qualitative treatment than to attempt quantitative precision.

It is far too early to decide whether or not catastrophe theory will be of major value in biology. That it provides useful and accurate descriptions of certain physical processes is now beyond question. More generally, the context for catastrophe theory is topology, and topological thinking has been of immense value in the understanding of many physical phenomena. It seems highly probable that the topological approach will prove invaluable in the study of biological processes as well, but this is an approach that can only be learned slowly, with trial and error. Zahler and Sussman have presented some valid criticisms of applied catastrophe theory, but their over-reaction is unfortunate. It leads them into exaggeration and wholesale rejection of very useful propositions.

R. BELLAIRS

University College London, UK

B. GOODWIN

M. R. MACKLEY

University of Sussex, UK

SIR,—The case in favour of catastrophe theory rests not on speculative models in the social sciences, but on successful applications to the physical sciences. In 1975 and 1976 there appeared approximately 42 papers applying catastrophe theory to physics, nine to biology, and 14 others: Sussmann and Zahler's criticisms deal almost entirely with one sociological paper, two on biology, and one model taken from two popular articles and a paragraph in a conference report. They do not hesitate to extend their conclusions to areas they have not studied: "we anticipate that

the results of an extended search (covering biology, linguistics, physics, or psychology) will be similar (that is negative)" from (Sussmann, H. J. & Zahler, R. S. *Proceedings of the 1976 biennial meeting of the Philosophy of Science Association, Chicago*, in press). Tim Poston and I have written a book (Poston, T. & Stewart, I. N. *Catastrophe theory and its applications*, Pitman, London, 477 pp.), due in print early in 1978, documenting quantitative applications in the sciences, which casts severe doubt on their conclusions. A major plank in their case—allegation of a repeated mathematical error—is refuted by Poston (*Mathematics Report*, Battelle Geneva (in press)). Their reliability may be judged by their statement: "Stewart repeats the untrue assertion that Zeeman's embryological predictions have been 'recently verified by experiment' ". What I wrote was: "... with the prediction that slowing down the chemical reactions of the primary wave would lead to the formation of fewer somites, an effect recently verified by experiment". Which happens to be true.

Similar misinterpretations vitiate many of Sussmann and Zahler's criticisms, rendering them analogous to disproving Pythagoras' theorem by exhibiting a triangle that is not right-angled. With the exception of their discussion of the nerve impulse model, few of their criticisms are conclusive, and some are simply wrong. Others are problems of general mathematical modelling, which can usually be resolved by reference to current scientific practice. Sussmann and Zahler's charges go considerably beyond anything they have correctly substantiated.

IAN STEWART

University of Connecticut,  
USA

SIR,—It would be a pity if the strong attack by Zahler and Sussman on some biological and sociological models based on catastrophe theory, (27 October, page 759) were to mislead readers into thinking that such new and beautiful mathematics has no useful application in any science. The fact is that in this laboratory catastrophe theory is being employed in the development of new concepts, in the explanation and prediction of phenomena, and in the design of experiments, in two areas of physics.

The first is short wave optics (and quantum mechanics) where Thom's theory classifies the forms of focal surfaces (caustics) and makes it possible to give a precise description of the finest detail in the associated diffraction patterns (Arnol'd, V. I. 'Critical points of smooth functions and their normal forms' *Uspekhi Mat Nauk*

(translation: *Russian Mathematical Surveys*) **30**, 1–75 (1975); Berry, M. V. 'Waves and Thom's Theorem' *Adv. in Phys.* **25**, 1–26 (1976); Duistermaat, J. J. 'Oscillatory integrals, Lagrange immersions and unfolding singularities' *Comm Pure App Math* **27**, 207–281 (1974)). The classification describes caustics that are 'structurally stable', that is those whose forms survive perturbation. This makes catastrophe theory particularly suited to the optics of nature rather than artefacts such as microscopes and telescopes whose focussing is dominated by cylindrical symmetry.

We have made progress in understanding the optics of irregular water droplet 'lenses' (Berry, M. V. 'Waves and Thom's Theorem' *Adv. in Phys.* **25**, 1–26 (1976); Nye, J. F. 'Optical caustics in the near field from liquid drops' (submitted to *Proc. Roy. Soc.*), the fine structure of swimming pool caustics (Berry, M. V. & Nye, J. F. 'Fine structure in caustic junctions' *Nature* **267**, 34–6 (1976)), atom scattering by crystal surfaces (Berry, M. V. 'Cusped rainbows and incoherence effects in the rippling-mirror model for particles scattering from surfaces'. *J. Phys. A* **8**, 566–84 (1975)) and the statistics of twinkling starlight (Berry, M. V. 'Focusing and twinkling: critical exponents from catastrophes in non-Gaussian random short waves' (*J. Phys. A*, in press)). This last application (which has proved peculiarly resistant to more conventional forms of analysis) makes essential use of the enormous extension of Thom's classification being developed by Arnol'd (Arnol'd, V. I. 'Critical points of smooth functions and their normal forms' *Uspekhi Mat Nauk* (translation: *Russian Mathematical Surveys*) **30**, 1–75 (1975)) in the Soviet Union.

The other area is fluid mechanics, where the elliptic umbilic suggested the design of the 'sixroll mill' (Berry, M. V. & Mackley, M. R. 'The sixroll mill: unfolding an unstable persistently extensional flow'. *Phil. Trans. Roy. Soc. (London)* **287**, 1–16 (1977)), a device for studying the effects of dissolved long-chain molecules on the flow of Newtonian fluid. The mill produces a sequence of flows with fully describable instabilities, and addition of polymer is dramatically revealed by changes in the topology of the pattern of streamlines. This specialised application has now been generalised (Thorndike, A. S., Cooley, C. R. and Nye, J. F. 'The structure and evolution of vector fields and other flow fields' (submitted to *J. Phys. A*)) into a comprehensive theory of flow patterns, which has already given insight into the structure of the geostrophic wind and the move-

ment of ice in the Arctic ocean.

These are genuine applications of catastrophe theory; they have led to advances in our understanding of the physical systems concerned. It is important to distinguish them from illustrations of the theory, where the mathematics is employed correctly (that is to systems satisfying its axioms) but in more sophisticated derivations of results already known; elastic buckling and the mean field

theory of phase transitions fall into this category. The applications should also be distinguished from what I shall call invocations of the theory, where it is employed because of the suggestiveness of its images in the hope that its axioms might eventually be shown to apply; perhaps it is towards this area that Zahler's and Sussmann's criticisms are really directed.

The six roll mill; experimental observations and computer simulations of the patterns illustrating elliptic umbilic critical point.

SIR,—While I do not wish to perpetuate unwarranted enthusiasm for the ability of catastrophe theory to transform the natural and social sciences, I believe that Zahler and Sussmann (27 October, page 759) have overstepped the bounds of decency in their vehement attack. Let me point out a few specific instances in which they seriously mislead the reader.

A fundamental error that they make is in the statement, "Catastrophe theorists agree that the term 'catastrophe' is reserved for certain kinds of singularity of smooth maps, seven of which have been described and classified elegantly by Thom". I can only conclude from this statement that Zahler and Sussmann have not read Thom's work. (There is no reference to Thom in the paper apart from his theorem). Thom describes the catastrophes which Zahler and Sussmann discuss as "elementary catastrophes" but repeatedly makes it clear that there are other kinds of catastrophe as well.

The authors' confusion on this point creates a straw man which they repeatedly flail in their article. For example, juxtapose the quote in the first paragraph of their paper with Thom's general definition of catastrophe and with their restricted one. The quote refers to a general approach to studying questions rather than the repeated use of a specific mathematical theorem, and makes much more sense in the context which was intended.

The section on 'Better alternatives' accuses catastrophe theory of ignoring the study of shock waves and bifurcation theory even though these are explicitly discussed in Thom's book, *Structural Stability and Morphogenesis* (Addison-Wesley, 1972), in which he lays out his theory in detail for the first time. I might add that one of the most successful applications of catastrophe theory has been to the study of shocks in a single convex conservation law (Schaeffer, D. 'Regularity theorem for conservation laws' *Advances in Mathematics* II 368–386 (1973) and Golubitsky, M. & Schaeffer, D. 'Stability of shock waves for single conservation law', *Advances in Mathematics* 16, 65–71 (1975)). In their portrayal of the scope and content of catastrophe theory, Zahler and Sussmann are simply wrong.

Let me turn to a second point. In a section entitled 'Careless discussion of evidence', Zahler and Sussmann quote Zeeman's statement: "Recent experiments by J. Cooke and T. Elsdale appear to confirm some of my predictions" (my italics). They then refute this statement with a quotation from T. Elsdale *et al.*, "we do not yet conclude that the observations here presented have confirmed Cooke and Zeeman's model to the exclusion of others" (my italics). The paper of T. Elsdale *et al.*, does indeed confirm some of the predictions of the Zeeman-Cooke model. It does not confirm the

model, but then Zeeman did not assert that it did. Zahler and Sussmann never say that these two statements contradict one another, but they clearly imply that Zeeman has made unsupported claims in his statement. This is false, and they try to mislead us into believing it.

At another point in their discussion, Zahler and Sussmann misrepresent the work of Kozak and Benham on denaturation of proteins. They assert that an essential feature of the work of Kozak and Benham is the 'delay rule' which predicts that there will be hysteresis in the denaturation-renaturation phenomenon. Yet Kozak and Benham do not rely upon this 'delay rule', and indeed use the 'Maxwell convention' throughout the second part of their three part work ('Denaturation: an example of Catastrophe II. Two-state transitions', *J. Theoretical Biology* 63, 125–149 (1976)). Zahler and Sussmann also criticise this model for predicting that the temperature denaturation curves have vertical slopes while the enthalpy change limits their steepness. Their criticism ignores the statistical discussion of Kozak and Benham which addresses the fact.

The thrust of this last criticism is also misplaced. A similar criticism could be made to the study of shocks in the solution of hyperbolic conservation laws, a phenomenon which is better understood mathematically. Real gases have viscosity, and viscosity prevents a truly discontinuous change in the velocity of the gas. Nonetheless, abrupt changes do occur. They can be modelled well by hyperbolic conservation laws which do allow discontinuous solutions. The addition of a term representing viscosity to the equations smooths out this discontinuity, and the behaviour of solutions has been studied as this viscosity term tends to zero. The conservation laws work well in giving approximations to real fluid flow. It is even the case, as we noted above, that catastrophe theory has described the shocks for the simplest (but only the simplest) conservation laws. The confusion of "the intuitive notion of 'jump' as a rapid change with the precise mathematical notion of a jump discontinuity" is not inherent to catastrophe theory, but is a common and useful approximation in many mathematical models.

I prefer to make a few remarks on the paper as a whole rather than continue to belabour specific failings. As a 'review article', Zahler and Sussmann review a single paper—their own. Their review is a summary and not a review. There are others who are more optimistic about the potential applications (and the past successes) of catastrophe theory than Zahler and

Sussmann are, but they have been ignored. Zahler and Sussmann have discovered that "catastrophe theory is a blind alley" because they have blinded themselves to anything hopeful that they might see. Surely a review of the "accomplishments of applied catastrophe theory" should not be so narrow. In particular, it should at least mention the work of J. M. T. Thompson on elastic stability (*Nature* **254**, 392-395 (1975)).

Zahler and Sussmann are also snide. They denigrate catastrophe theory for the "large number of (mostly unrefereed) publications praising each other extravagantly". This is an attempt at character assassination due to the fact that many papers are published in conference proceedings. I

think the remark is out of place—indeed I think the whole paper is out of place. It is deceptive, and it is not what it purports to be. There is much to be criticised in work which has been done using mathematical models based upon catastrophe theory, but the criticism of Zahler and Sussmann is merely mean spirited.

JOHN GUCKENHEIMER

*University of California, Santa Cruz*  
SIR,—My paper, to which Zahler and Sussmann refer, was presented as a discussion paper at a meeting of the New York Academy of Sciences. It was directed to a general audience at a time when catastrophe theory was not widely known. Since I could not presume a detailed knowledge of the theory or of biology, I intended to give

simplified explanations of both so that I might suggest possible uses of the theory in biology.

May I also suggest that one illustration of a catastrophic jump might be the apparent discontinuity in Sussmann's opinion of Zeeman's paper (in *Towards a Theoretical Biology* **4** (1972)). In 1975 Sussmann (*Synthese* **31**, 229 (1975)) writes "in most applications what is used is not catastrophe theory as a set of results, but catastrophe theory as a conceptual framework (for an example, see Zeeman's beautiful paper in *Towards a Theoretical Biology* on heartbeat and nerve impulse)". Now, writing with Zahler he expresses a very different opinion.

*Williams College, Massachusetts, USA*

## Censuring repressive regimes

SIR,—Every four years the International Union Against Cancer organises a huge international cancer congress, typically attended by perhaps 6,000 scientists. The next one is scheduled for 5-12 October 1978 in Buenos Aires, Argentina. However, in *Science* (21 October) and *Nature* (3 November, page 8) groups of scientists, including two recent Nobel prize-winners for medicine, have called on other scientists to boycott this conference because, it is claimed, "scientists, physicians, professors, journalists, intellectuals, and other (Argentinian) citizens have been arrested, imprisoned without benefit of *habeas corpus*, often tortured and sometimes executed without trial". These allegations are supported by editorials in *Nature* (**263**, 452; 1976 and **266**, 395; 1977).

We were telephoned by the press for comment on these letters, but could not comment because, like many other full time scientists, we were necessarily ignorant of conditions in most foreign countries. We therefore made contact with Amnesty International (AI), in the hope of securing some reasonably unbiased data. The 'Report of the AI Mission to Argentina' (1977) and the detailed letter which the Director of AI sent us appear to be objective and impartial, and the conditions they describe are really appalling.

Briefly, there was a military coup in March 1976. During the next six months about 2,000 Argentinians were killed by the government or (almost equivalently, it seems) disappeared. Killings and disappearances of non-violent Argentinians (a priest, for example, who said a requiem mass for a parishioner who had been killed by government agents) continue at a rate

of hundreds a month, and frequently bodies are discovered, some of people recently arrested, many with evidence of severe torture. Recent Argentinian laws explicitly forbid newspapers to report, comment on or make reference to abductions or the discovery of bodies, and also forbid propagation through any medium whatever of news or views with the purpose of lessening the prestige of the armed forces!

In the apparently impartial opinion of the Director of AI (personal communication, 25 October), "the state of affairs in Argentina is now one of the most serious in the world: Argentina has probably, since March 1976, the largest number of prisoners of conscience, disappearances and political killings in the whole of Latin America". (In most cases, according to AI, those affected were not terrorists.) However, even if, among many bad countries, Argentina is worst in this respect, it does not follow that a boycott is wise, for it is difficult to estimate the true probabilities of all its possible effects (especially if one is distracted by suppositions about the motives of the scientists who propose it or of those who oppose it).

It must be recognised by the proponents of any boycott that it is very unlikely to have much impact on the repression of non-violent citizens, while the opponents of a boycott must equally concede that there does exist a small probability that it would materially accelerate humanitarian progress. Balancing these considerations are the medical advantages of holding a cancer congress, but here a rather curious analogy exists; one single congress is very unlikely to have much impact on human cancer, but there does exist a small probability that it will materially accelerate medical progress. Moreover, because the Argentinian junta are apparently (*Financial Times*, 14 September) having difficulty,

because of their human rights record, in securing foreign investment and arms, it is uncertain which probability is smaller in this particular balance.

One must also ask, however, if scientific meetings are boycotted, where it will all end. In a related academic field, for example, the International Epidemiological Association will meet in Iran in 1979 and, overall, a large number of international scientific meetings take place in countries with governments which kill, or torture, or imprison non-violent citizens. If these several meetings were all avoided, so many different governments would thus be censured that none would thereby be singled out for special attention, and the net effect might merely be to forfeit the rather useful apolitical image which science has earned, while achieving little or no humanitarian progress. It might be practicable just to boycott those governments which persecute many scientists, but this seems rather artificial, and might merely aggravate anti-science sentiments. Moreover, the scientists who live in some of the countries concerned might much rather have a week or two of contact with the international community than suffer continued intellectual isolation. Perhaps, anomalously, boycotts do more harm than good in states with closed frontiers (unless the state would also restrict free attendance), but perhaps they are occasionally useful in states with open frontiers.

Advice and comments from other scientists, especially those who, unlike ourselves have actually worked under repressive regimes, would be timely, both about the general advisability or inadvisability of such boycotts (ignoring everybody's motives, please), and also about the specific 12th Cancer Congress in Argentina next year.

## Object Kowal, the most distant asteroid

from David W. Hughes

ASTEROIDS often get into the news. Only 2 years ago asteroid 1976 AA was found to be the first with a mean distance from the Sun less than that of the Earth. On 1 November this year slow-moving object Kowal was discovered and has subsequently been found to have the largest known orbit of any of the asteroids. It is orbiting the Sun between Saturn and Uranus.

Charles T. Kowal of the Hale Observatories, California Institute of Technology is carrying out a systematic survey of the outer solar system by photographing regions of the ecliptic using the 122-cm Schmidt telescope on Mount Palomar. He first spotted this strange asteroid when examining photographic plates that he had taken 2 weeks previously on 18 and 19 October. It was also discovered on the plate that had been taken by Tom Gehrels (University of Arizona) on 11 October.

Bodies in the Solar System appear to move across the sky against the backdrop of the vastly more distant, 'fixed' stars. A long-time exposure will thus produce a trail-of-light image for the Solar System objects as opposed to a point image for the stars. Also the positions of the objects change from one plate to the next. These trails can be detected by the use of microscopes.

Slow-moving object Kowal has an angular motion of only 0.0149 degrees per day, a speed scarcely greater than that of Uranus. As objects in the Solar System with near circular orbits have a mean daily angular motion proportional to  $a^{-3/2}$  where  $a$  is the semi-major axis of their orbit, this automatically means that object Kowal is in the outer reaches of the Solar System, near the orbit of Uranus. On 18 October it had a right ascension of  $2^h 05^m$  and a declination of  $+12^\circ 09'$ , placing it about half-way between Alpha Aries and Alpha Pisces. If the positions of the object on a set of dates are known,

its orbit can be calculated. Object Kowal has, however, moved only about three-quarters of a degree around its orbit since its discovery, thus making the orbital determination very inaccurate. Brian G. Marsden (Smithsonian Astrophysical Observatory, Cambridge) has published a preliminary calculation in Circular 3129 of the International Astronomical Union's Central Bureau for Astronomical Telegrams. This orbit is shown in Fig. 1. It has a low eccentricity, 0.031, a low inclination to the ecliptic,  $5.2^\circ$ , a peri-

helion distance of 15.836 AU, a semi-major axis of 16.340 AU, and a period of 66.1 years.

The object is extremely faint, having a visual magnitude between 18 and 19, this faintness being one of the reasons it has previously gone undiscovered. If it has the orbit shown in Fig. 1 its magnitude will change by only 0.5 over one period. There are thus very few telescopes capable of searching for such objects, those that can find them having to have an objective lens more than 100 cm in diameter.

Fig. 1 The orbit of slow-moving object Kowal and the position of this new asteroid with respect to Earth, Jupiter, Saturn and Uranus. The hatched area is the main asteroid belt.  $\gamma$  is the first point of Aries.

David W. Hughes is a Lecturer in the Department of Physics at the University of Sheffield.

Even though object Kowal is faint, it is much brighter than any known comet would be at that distance. It has thus been concluded that it is an asteroid. It might even turn out to be the first of a new belt of asteroids orbiting between Saturn and Uranus. Most asteroids orbit the Sun in a broad belt between Mars and Jupiter (shown as a hatched area in Fig. 1). Some have larger orbits, Hidalgo for example has a highly eccentric orbit which approaches the orbit of Saturn. It must be remembered of course that the further away from the Sun and Earth an asteroid is, the more difficult it is to detect. The region between Saturn and Uranus could easily contain an Earth's mass worth of asteroids which have remained undetected until now.

The brightness of the asteroid can be

used to estimate the product of its albedo and its reflecting surface area. Asteroids seem to have albedoes ranging from about 0.035 to 0.27. As the albedo of object Kowal is unknown the size cannot be found accurately. It has been estimated to have a radius in the region 80–320 km. The largest asteroid, Ceres, has a radius of 380 km, and so object Kowal is definitely at the top end of the asteroidal mass scale.

Where do we go from here? More observations of object Kowal, stretching forward in time, or even lying unknown on photographic plates, will enable a much more accurate orbit to be calculated. Also now astronomers know that at least one asteroid, albeit a large one, is orbiting between Saturn and Uranus it is most likely that more will be discovered in the near future. □

## Workshop on hydrophobic effects

from Felix Franks

A workshop on Hydrophobic Effects was held at the 5th International Conference on Chemical Thermodynamics, Ronneby, Sweden, 23–26 August, 1977.

THE involvement of so-called hydrophobic effects in the maintenance of biological structures has been recognised for many years; G. S. Hartley first used the term in his analysis of micellar aggregation. The detailed nature of the environment of alkyl chains in water, and the manner in which their interactions give rise to supermolecular structures and promote the unique folding of biopolymers, are not yet too clear. Nevertheless, over the past 10 years a considerable effort has been devoted to studies of dilute aqueous solutions of alkyl derivatives. The workshop was arranged in an attempt to reach some agreement on terminology and symptoms of hydrophobic effects and to analyse those features which play a part in biochemical processes.

The question of suitable and correct standard states was discussed at length; for means of comparison, the transfer of an alkyl group from the ideal gas state to an infinitely dilute aqueous solution is the most useful process to consider, and the term 'hydrophobic solvation' was used to describe such a process. Although solution concen-

tration is commonly expressed in terms of mol fraction or molality, it was pointed out that the correct way of comparing solute environments in different solvents is through the molarity concentrations. This is also required for statistical thermodynamic treatments of solute-solute interactions, since the equations describing solution behaviour are referred to constant volume, rather than to constant pressure.

The standard thermodynamic functions of solvation which characterise the transfer of an apolar solute from the ideal gas to an infinitely dilute aqueous solution include a positive free energy which arises from a large, negative entropy, a negative volume and a very large, positive heat capacity. In fact, the limiting partial molar heat capacity of an alkane in aqueous solution is three times as large as the heat capacity of the alkane in its pure liquid state. Taken together with recent nuclear magnetic relaxation and computer simulation data, the heat capacities are consistent with the picture of a rotation of water molecules away from the alkane, with possibly slight deformations in the tetrahedral hydrogen bonding geometry, to give rise to cavities which can accommodate the hydrophobic groups. The hydrogen bonding regime which normally exists in liquid water is but slightly modified; whatever modification does take place is responsible for the negative entropy and the positive heat capacity of hydrophobic solvation.

Interactions between solvated alkyl residues can be studied at different

levels, ranging from pairwise solute effects to the complete removal of water and its substitution by a hydrocarbon. For the latter process the standard free energy of transfer is about  $-3.45$  kJ per mole  $\text{CH}_2$  groups. Intermediate between these two environments are the micelle, the phospholipid bilayer membrane and the interior of a globular protein. None of these three biologically important structures can be equated to the bulk hydrocarbon, and therefore free energy data relating to the transfer of alkyl groups from water to hydrocarbon should not be used for thermodynamic calculations of micellisation or protein unfolding. The hydrophobic pair interaction is considered to be an adequate model for enzyme-substrate interactions and for the contributions of exposed apolar amino acid residues to protein stability (or instability).

The thermodynamic functions describing such pairwise interactions are obtained as second virial coefficients from the limiting slope of the concentration dependence of the various excess functions. Recent excess volume ( $\Delta V^E$ ), heat capacity ( $\Delta C_p^E$ ) and compressibility ( $\Delta \kappa^E$ ) measurements on very dilute solutions indicate that these second virial coefficients have the opposite signs to those expected from the classical treatment of the hydrophobic interactions. Indeed,  $\Delta C_p^E$  is a very complex function of concentration and temperature. It seems that the hydrophobic pair interaction is qualitatively different from the interaction involving large numbers of alkyl chains, for example, micelle formation.

A comparison of gas and solution second virial coefficients of  $\Delta G^E$  shows that the interaction between pairs of alkyl groups in dilute aqueous solution is weaker than the corresponding interaction in the gas phase. Also, recent experiments with non-aqueous solvents (for example, dilute solutions of octane in N-methylacetamide or hydrazine) indicate the existence of a general solvophobic effect which differs from the hydrophobic effect in two aspects: it does not originate from a negative  $\Delta S^E$ , and it is not associated with a large positive  $\Delta C_p^E$ , both of which effects characterise the hydrophobic interaction. With rise in temperature water becomes more hydrophobic, and near  $150^\circ\text{C}$  its behaviour approaches that of 'normal' polar solvents.

So far only limited progress has been made in the molecular description of hydrophobic effects by means of suitable potential and radial distribution functions. Any useful interpretation of terms such as 'water structure making', commonly found in the literature, must await the development of credible radial distribution functions. In the meantime it is being recognised that

the 'interaction' between alkyl groups in water results primarily from repulsions between water and solute, and not from van der Waals attraction between solute molecules.

Most molecules for which hydrophobic effects are commonly invoked also possess one or more functional groups which contribute to the observed interactions in solution. In all cases such contributions of  $-\text{CONH}$ ,  $\text{CHOH}$ , and so on to  $\Delta G^\text{E}$  are negative, but only alkyl groups exhibit negative contributions to  $\Delta S^\text{E}$ . Even more important, cross interactions between alkyl and polar groups are not equal to the mean of the interactions between like groups. This finding has a bearing on calculations of protein stability in terms of amino acid side chain contributions.

Any future progress in our understanding of hydrophobic effects is not likely to come from thermodynamics, although there is still much scope for high precision measurements of excess functions in the low concentration range. Techniques which are showing promise include electron spin exchange between hydrophobic spin probes and the enhancement of nuclear magnetic relaxation by such paramagnetic spin probes. Monte Carlo and molecular dynamics simulations have also shown some promise, but in the absence of reliable potential functions it is questionable how much confidence can be attached to the results of such calculations. The same question mark hangs over recent computer simulations of protein dynamics, in which solvation and hydrophobic contributions to the stability of the folded protein were not, and indeed, could not be included. However, in view of the progress that has been achieved over the past 10 years in our general understanding of molecular interactions in aqueous solutions, the prospects for such ambitious ventures look quite encouraging.  $\square$

### A hundred years ago

THE chemists of Berlin have been occupied lately in analysing the wares of the wine merchants, and no little excitement has been caused by the discovery that the entire stock of one of the largest houses dealing in wines for medicinal purposes, consisted entirely of artificially prepared mixtures of spirit and sugar solutions, flavoured with various herbs.

From *Nature* 17, 29 November, 1877.

## Mechanisms of parasite immunity

from F. E. G. Cox

A meeting on Immunity in Parasitic Diseases: Antigens and Mechanisms of Immune Response was held under the auspices of the Institut National de la Santé et de la Recherche Médicale and the Institut National de la Recherche Agronomique with Professor André Capron as Chairman, at Grignon, France on 5-9 September, 1977.

PARASITOLOGISTS and immunologists need to meet from time to time to share their rapidly accumulating knowledge and there can be few better places to do so than a Louis XIII château. Twenty review papers and four round tables, each with a dozen or more contributors, demonstrated the healthy state that the science of parasite immunology has reached and for the first time various pieces of information painstakingly obtained in different laboratories began to fall into place. The two themes that came over time and time again were first that in each infection there are probably several effector mechanisms involved in immunity and that under particular circumstances any or all of these might be involved and, second, that eosinophils, macrophages, antigen-antibody complexes and complement may be more important to parasitic infections than hitherto suspected. Against this background it was possible to look forward as well as backward.

The initiation of any immune response begins with the antigens of the parasite. Most parasite antigens studied so far have been relatively crude extracts and Ruth Arnon (Weizmann Institute of Science, Rehovot) discussed the possibilities of obtaining pure antigens which could be characterised and synthesised. For some microorganisms this possibility is a reality and for many parasites there are indications that the isolation and characterisation of functional antigens has progressed sufficiently far for the synthetic stage to be contemplated. The isolation of such antigens depends on the exploitation of their characteristics such as enzymatic activity and ability to bind to drugs and ligands and P. Pery (Grignon) showed that this was not difficult to achieve. In the case of *Schistosoma mansoni* over 60 antigens have been identified. D. Bout and his colleagues at Lille, using drugs as

ligands, have found that malate dehydrogenase is a particularly important antigen in human *S. mansoni* infections and J. P. Rotmans (University of Leiden) has shown that only one isoenzyme of malate dehydrogenase is antigenic in mice. This antigen can be purified and used in microgram quantities in immunodiagnosis of schistosomiasis. An egg antigen described by J. Hamburger (Jerusalem) is the antigen responsible for granulomas in mice but also has considerable potential in immunodiagnosis as has a circulating polysaccharide antigen isolated by Y. Carlier and his coworkers at Lille. Other purified antigens also described include one from *Nippostrongylus brasiliensis* (A. Petit *et al.*, Grignon) and one from *Trypanosoma cruzi* which, as it is shared by both the blood and culture forms of this parasite, may be very useful as a potential vaccine (L. Hudson and D. Snary, Wellcome Laboratories, Beckenham).

The effector mechanisms attracted considerable attention particularly in the case of schistosomiasis. A. Capron (Lille) drew attention to the two main ways in which schistosomes are attacked, IgG and eosinophils and IgE and macrophages. The IgG involved is IgG2a and the activity of the eosinophils is enhanced by the presence of mast cells (Monique Capron *et al.*, Lille). The importance of eosinophils in immunity to parasites was discussed in general terms by A. B. Kay (Edinburgh) and in much more detail as the cells that actually attach to schistosomes and penetrate the body wall by C. Mackenzie *et al.* (National Institute for Medical Research, London) who pointed out that these cells adhere to other helminths as well. B. M. Ogilvie (NIMR) also drew attention to the similarities in the immune responses to parasites as different as *Elmeria* and *Nippostrongylus* living in the gut.

Macrophages are obviously important in immunity to parasites and their role in the production of nonspecific mediators of immunity was discussed by A. C. Allison (Clinical Research Centre, Harrow). Nonspecific immunity to blood parasites following the administration of *Corynebacterium parvum* or BCG was also discussed by F. E. G. Cox (King's College, London), who postulated a common mechanism for homologous, heterologous and non-specific immunity to malaria in rodents, and by B. Leblanc and J. C. Salmon (Villejuif). Another nonspecific mechanism, the activation of complement through the alternative pathway, was discussed by G. Hultdt (Stockholm) in the context of *Entamoeba histolytica*.

Immunodiagnosis and vaccination are the two main objectives behind immunological studies and the prospects

F. E. G. Cox is Professor of Zoology at King's College, London.

for vaccination were discussed by D. S. Rowe (World Health Organisation, Geneva) but it is too early yet to assess the potential of purified or crude antigens as vaccines against the more important parasitic diseases. The successful vaccination of cattle and sheep against *Schistosoma bovis* using irradiated whole larvae was described by M. G. Taylor (St Albans) but a more cautionary story was told by G. M. Urquhart (University of Glasgow) who discussed the success of the irradiated *Dictyocaulus viviparus* vaccine and the lack of success with a similar *Ancylostoma caninum* vaccine which was due not to any defect in the vaccine but to the fact that American veterinarians preferred drugs which are very effective against this worm. For most of the parasitic diseases of man effective drugs are not currently available and until they are immunological research must not be allowed to decline; those present at the Grignon meeting will ensure that this does not happen. □

## Fly's eye view of cosmic rays

from K. J. Orford

AN interesting and elegant new experimental technique, designed to take 'pictures' of the tracks in the atmosphere of very high energy cosmic rays, has borne its first fruit. The results of a pilot experiment (Bergeson *et al.* *Phys. Rev. Lett.* **39**, 847; 1977) have demonstrated that such tracks may be observed using the very weak atmospheric nitrogen fluorescence light. Its significance is that the effective size of detectors of the very rarest cosmic rays has been increased by this technique to the volume of the atmosphere which can be seen from a point on the ground.

The main aim is to measure the energy spectrum of cosmic rays up to energies difficult to attain with any other technique. A continuous spectrum of energies is found to come from all parts of the sky up to an energy of about  $10^{20}$  eV (about 16 J) per particle. The cosmological problems centre on the sources of these particles, whether they are local or universal, and on how much such prodigious energies can be given to individual particles. If, for example, these cosmic rays are universal, then a limit is placed on the energy spectrum. At an energy near  $6 \cdot 10^{19}$  eV a proton will interact strongly

with the 2.7 K universal microwave background, and will lose a large amount of energy. The spectrum will then rapidly fall in the region of  $10^{20}$  eV. There are indications from current experiments that it does not (Cunningham *et al.*, *15th Int. Conf. on Cosmic Rays*, Plovdiv 1977), at least up to nearly  $10^{20}$  eV.

Just to detect the arrival of these cosmic rays is very difficult, mainly as a result of the small flux. A cosmic ray of energy greater than  $10^{20}$  eV falls on a square kilometre somewhere between once per year and once per century, such is the present uncertainty. Such a low rate is detectable only because the cosmic ray particle causes a shower of up to  $10^{11}$  electrons and other particles to build up along its track as it passes through the air. This shower has a lateral extent of a square kilometre or more, enabling particle detectors to be widely spaced on the ground to provide samples of the shower particles. For about 20 years, ever larger arrays of such detectors have been deployed around the world to sample large showers.

Some of the best information to date has come from the UK array at Haverah Park, near Harrogate. This has a sampling area of 12 square kilometres and has recorded showers of energy up to  $10^{20}$  eV. However, there is a limit to the size which such arrays can be made, the cost increasing with the area covered.

The new technique uses the whole atmosphere visible from any point as a detector. It exploits the fact that most of the energy of the primary cosmic ray does not reach the ground, but is dissipated as ionisation in the air. About 0.05% of this energy is released as nitrogen fluorescence light which produced a very short ( $\mu$ s) flash of light along the cosmic ray track. A detector designed to measure this flash was first proposed in 1965 (Greisen *Int. Cosmic Ray Conf.*, London, 1965). However, the technical problems are severe. The light output is very small and difficult to detect against the background light of the night sky (each electron in the shower gives only four fluorescence photons per metre of track).

The pilot experiment of Bergeson *et al.* involved the use of concave mirrors of 1.5 m diameter, each focusing a small section of sky onto the faces of 12 photomultipliers. Each tube views an area of sky about  $6^\circ$  across. Showers detected by a conventional particle array at Volcano Ranch, New Mexico, were compared with the images seen by the mirror assemblies and found to be in agreement. Following this, a full-scale experiment is being constructed on a mountain top in Utah, consisting of 67 mirror units. Thus a whole sky

image is obtained with a resolution of better than 0.007 steradians. This many-faceted experiment, early dubbed the 'Fly's Eye', should detect the highest energy showers at a distance of 50 kilometres. The effective collecting area of about 8,000 square kilometres should allow an energy spectrum to be measured with high statistical precision.

This would be enough by itself to justify the experiment, but other results of no less significance may be forthcoming. Because the track of ionisation is seen for most of its length, the point at which the primary cosmic ray particle first interacted with a nucleus in the air may be found. The observation of a large number of such points should reveal the mean free path of the primaries for interaction in air, and hence their atomic weight. The composition of high energy cosmic rays is at present an open question, and compositions other than a simple 100% proton flux bring their own problems concerned with production, acceleration and propagation from the sources to the Earth.

Finally, the mean free path of the primaries could enable the total cross section for nucleus-nucleus, and from that possibly proton-proton, interactions to be found at energies more than  $10^7$  times higher than those at present available. □

## Negative strand viruses

from T. Barrett

A meeting on Negative Strand Viruses and the Host Cell was held at King's College, Cambridge, from 1-5 August, 1977. The proceedings will be published by Academic Press early in 1978.

NEGATIVE strand viruses are responsible for many important human and animal diseases, including influenza, Lassa fever, measles, mumps, distemper, fowl pest and rabies. This group of viruses has in common the possession of a single-stranded RNA genome which is of opposite polarity to the messenger RNA (mRNA). One of the most striking points brought out at the meeting was the great advance that has been made in the understanding of the nature of the genome of these viruses, in particular the genome of the influenza A viruses which consists of

eight separate genes. Many speakers reported methods developed to assign functions to the individual genes. P. Palese (Mount Sinai School of Medicine, New York) is mapping gene functions of influenza B strains. Unlike the A strains, the B strains do not undergo dramatic antigenic shifts and do not cause pandemics. However, like the A strains they contain eight gene segments and eight virus-specific proteins can be detected in virus-infected cells.

The genome of the bunyaviridae was discussed by D. H. L. Bishop (University of Alabama). These are arthropod-borne viruses, some of which, for example California encephalitis virus, cause disease in humans. The genome consists of three segments; two of the segments code for two virus polypeptides while the third codes for two virus glycoproteins, probably through a polycistronic message.

The segmented nature of the influenza virus genome makes it an ideal candidate for sequencing studies because individual genes can readily be isolated. P. Fellner's group (Searle, High Wycombe) in collaboration with groups in Cambridge and Mill Hill, is sequencing the two smallest genes, 7 and 8. Both have a characteristic U<sub>6</sub>A sequence near the 5' end of the viral RNA (vRNA). In prokaryotes a similar sequence is associated with transcription termination (Rosenberg *et al. Proc. natn. Acad. Sci. U.S.A.* **73**, 717; 1976) but in this case at the 3' end of the transcribed RNA rather than at the 5' end of the template. It seems that the polyadenylated messenger complementary RNA (cRNA) of influenza virus is not a full length transcript of the vRNA and the extra sequences at the 5' end may be important as recognition sites for the viral replicase. In contrast, unpolyadenylated cRNA is a full length copy of the vRNA and is presumably the template for new vRNA synthesis (A. Hay, National Institute of Medical Research, London, and R. M. Krug, Memorial Sloan-Kettering Cancer Center, New York).

Negative strand viruses with unsegmented genomes seem to have only one promoter site, and the positions of the genes in relation to the promoter site have been determined in some cases using the ultraviolet transcriptional mapping technique. The sequences of the ribosome-binding sites of all the mRNAs of vesicular stomatitis virus (VSV) have been determined by J. K. Rose (Massachusetts Institute of Technology). All contain a single AUG initiation codon. The cap structure for the N, NS and L protein mRNAs was found by ribosomes in the initiation complex and showed a 9-nucleotide homology in the first 11 nucleotides extending from the 5' end. In contrast, the binding sites of the M

and G protein mRNAs differed both from each other and from those of the other mRNAs and did not include the cap structure. This observation has an interesting physiological aspect because translation of the M and G proteins is more sensitive to hypertonic shock (Nuss & Koch *J. Virol.* **17**, 283; 1976). A possible mechanism for this suggested by Rose is that, in the case of these two mRNAs, the ribosome needs to move to the binding site and this step may be sensitive to salt.

#### Transcription and translation

Genome transcription and translation was a major topic of the meeting. A. K. Banerjee (Roche Institute, Nutley, New Jersey) proposed that synthesis of a leader RNA sequence before any mRNA synthesis, as described for VSV and Newcastle disease virus (NDV), may be a general strategy for the initiation of RNA synthesis by negative strand viruses with unsegmented genomes. All leader RNAs studied are approximately the same size and their compositions are similar. However, hybridisation studies show that there is virtually no sequence homology. The 3' end of the VSV genome has a high U content and more than half the leader sequence is composed of A residues. This probably functions as a recognition site for the virion-associated RNA polymerase. These virus genomes can be transcribed efficiently *in vitro* using a virus-associated polymerase.

A. J. Hay, T. Barrett (University of Cambridge) and J. M. Taylor (Institute for Cancer Research, Philadelphia) all found evidence for transcriptional control of individual cRNA species during influenza virus replication. Hay found that the amount of unpolyadenylated cRNAs, presumably the templates for vRNA synthesis, were produced in roughly equal amounts for each segment while the polyadenylated cRNAs, presumably the mRNAs, were produced in different amounts for each segment. Barrett and Taylor both described the preparation of cDNA copies of influenza virus RNA made using reverse transcriptase, which are being used to study the time course of vRNA synthesis.

J. Content (Institut Pasteur, Brussels) described a coupled cell-free transcription/translation system for influenza virus capable of producing authentic virus proteins *in vitro*. The proportion of viral polypeptides obtained *in vitro* was consistent with translation of primary RNA transcripts.

L. A. Ball (University of Connecticut) reported that six virus-specific gene products of NDV were faithfully expressed when both transcription and translation were carried out *in vitro*.

Ball also used the ultraviolet transcription mapping technique to determine the number of promoter sites and the gene order of NDV. The results were consistent with a single promoter site and a gene order of 3'-NP-F<sub>0</sub>-M-HN-L.

The assignment of virus cores to the conflicting demands of virus assembly and RNA synthesis was the subject of a stimulating talk by D. W. Kingsbury (St Jude Children's Hospital, Memphis). He has isolated two metabolically distinct virus core populations, free and bound, in Sendai virus. The bound fraction, inactive in RNA synthesis, contains the newly assembled cores and is likely to be the source of both the cores that enter the virion and those that become active in RNA synthesis. The free cores, active in RNA synthesis are an older population. Kingsbury suggested that a maturation process whereby more P and L protein is added to the core determines its assignment to the free RNA synthesising fraction and that once a core engages in RNA synthesis it is committed to remain within the cell and cannot be encapsidated.

H. Lodish (Massachusetts Institute of Technology) reported on the glycosylation of the virus glycoproteins at different stages in their journey from the rough endoplasmic reticulum to the cell membrane, from which they are finally incorporated into the virion. The unglycosylated form (G<sub>0</sub>) could only be detected by translation *in vitro*. A partially glycosylated form (G<sub>1</sub>), lacking the terminal sialic acid, could be detected on the rough endoplasmic reticulum, while the fully glycosylated form (G<sub>2</sub>) was detected on the smooth endoplasmic reticulum, the plasma membrane and in the mature virion.

#### Virulence

One of the most interesting sessions of the meeting was concerned with aspects of virulence. Although this is a very active area of research, no clear picture of the molecular mechanism underlying virulence has emerged. H. D. Klenk (Institut für Virologie, Gießen) reported that NDV strains differ with respect to cleavage of their glycoproteins and these differences are an important factor underlying variations in NDV pathogenicity. With virulent strains of NDV, cleavage and production of infectious virus occurs in all host cells analysed, while with avirulent strains this is the case only in a few host systems. However, with influenza virus, although cleavage of the glycoproteins is indispensable for the formation of infectious virus particles, other factors also influence virus virulence. R. Rott (Giessen) suggested that a gene constellation determines virulence in the influenza virus because, as a rule,

infection with recombinants with multiple gene exchanges produces less severe clinical illness. A multigenic determination of virulence was also favoured by J. L. Schulman (Mount Sinai School of Medicine, New York) who found that in random recombinants of a low yielding and a high yielding strain of influenza virus the genes for proteins NP, M and NS were selected in recombinants which replicated in high titres while no such selection for P genes was observed. W. J. Bean (St Jude Children's Hospital, Memphis) found that virulent recombinants always contained the NP gene from the virulent strain and, in contrast to Schulman's findings, gene 3 which codes for one of the P proteins. J. Oxford (National Institute for Biological Standards, London) isolated a clone derived from recombinants of virulent and avirulent human influenza strains which contained all the genes, except the two coding for the surface glycoproteins, from the avirulent parent but which was virulent for man. It seems that some fine coordination exists between the genes for the internal proteins of influenza virus whose balance can be upset either by mutation or recombination. This set of genes is in turn dependent on the two surface antigens for its expression.

#### Defective particles

Defective interfering virus particles are aberrant virus particles which lack parts of the virus genome and are produced when virus is passaged at high multiplicities. These DI particles interfere with the replication of normal virus particles and could be a host defence mechanism. That a host function is required for DI particle formation was shown by C. Y. Kang (University of Texas, Dallas) who found that VSV DI particles could not be produced in cells pretreated with actinomycin D, while if present in the inoculum DI particles can be replicated in the presence of the drug. DI particles can be derived from either the 5' or 3' ends of the non-defective genome. Those derived from the 5' end are capable of only a very limited RNA synthesis *in vitro* and are thought to inhibit the non-defective virus at the replicase level. J. Perrault (University of California, San Diego) and D. Kolakovsky (University of Utah, Salt Lake City) described DI particles derived from the 5' ends of VSV and Sendai virus, respectively, with inverted complementary terminal sequences. These inverted complementary sequences at the 5' end presumably confer a replicative advantage on the DI particles, since synthesis of both plus and minus strands could be achieved by the same replicase which normally recognises the

sequences at the 3' ends of the minus and plus strands.

R. A. Lazzarini (National Institutes of Health, Bethesda) described another type of DI particle of VSV derived from the 3' end of the genome. This DI particle has a leader RNA sequence and the genome is transcribed into 12–17S mRNA *in vitro* and *in vivo* without a helper virus. It lacks the greater part of the L-protein gene which is nearest the 5' end of the non-defective genome. In mixed infections, in addition to interfering with the replication of the infectious virus, it can augment the production of virus proteins, a phenomenon which may in some way trigger an enhanced immune response by the host. Clearly DI particle formation and its mode of interference is a complex process and one which will become increasingly important from the point of view of their possible role in the treatment of virus diseases. □

## Nuclear radii and magnetic moments by laser spectroscopy

from P. E. Hodgson

THE charge and matter distributions of nuclei, and their magnetic moments, are important features of nuclei, and many efforts are being made to determine them with increasingly high precision. It is often instructive to see how they change through a series of isotopes of the same element, but such studies are limited by the availability of the separated isotopes in sufficient quantities for accurate measurement. This makes it desirable to develop methods that are applicable to very small quantities of the isotope, so that measurements can be carried out on rare and on radioactive isotopes.

One of these methods uses high resolution laser spectroscopy, and the results of a determination of the nuclear radii and magnetic moments of  $^{129}\text{Ba}$  and  $^{131}\text{Ba}$  in this way has recently been reported by Nowicki and colleagues from the Nuclear Research Centre at Karlsruhe (*Phys. Rev. Lett.* **39**, 332; 1977).

The isotopes of barium were produced by (d,xn) reactions and subsequent  $\beta$ -decay from enriched  $^{130}\text{Ba}$  and  $^{134}\text{Ba}$ . The isotope  $^{131}\text{Ba}$  was also produced by neutron irradiation of enriched  $^{130}\text{Ba}$  in a nuclear reactor. The isotopes were enriched by an electromagnetic mass separator. This produced between 1 and 10 ng of the

isotope, sufficient for the laser method. The sample was in each case placed in an atomic-beam oven to produce a collimated beam of atoms. There is a second reference beam using the natural isotopic mixture. Light from dye lasers is passed through the atomic beams and this enables the hyperfine structure of a selected transition to be determined.

In this work the hyperfine structure of the 553.6 nm resonance transition  $6s^2\ ^1S_0-6s6p\ ^1P_1$  was measured by resonance fluorescence. The frequency of this transition, and indeed of all transitions, is slightly affected by the spatial extent of the nuclear charge distribution, and a quantum mechanical analysis shows that the shift in the frequency is proportional to the mean square radius of the charge distribution. The change in frequency from one isotope to another is thus proportional to the difference between their mean square radii.

This experiment gave for the mean square radius difference between barium 131 and 130 a value of  $-0.006\text{ fm}^2$  and between barium 130 and 128 a value of  $0.022\text{ fm}^2$ . These results are shown in the figure, together with corresponding values for other isotopes. This shows that the general trend of the charge radii continues smoothly for the even isotopes and that the large odd-even staggering is markedly reduced at neutron number 75. The magnetic moment can also be calculated from the hyperfine splitting, and a value of  $-0.714\ \mu_N$  is found for  $^{131}\text{Ba}$ . □

Differences of mean square radii of the barium isotopes as obtained from optical isotope shifts. The straight line shows the dependence to be expected from a standard homogeneous sphere.

## Study of membrane permeability changes by fluctuation analysis

Charles F. Stevens\*

*The molecular basis of the changes in membrane permeability that underlie the nerve impulse can be studied by statistical analysis of the random fluctuations in current through the nerve membrane. Such "noise analysis" has already begun to clarify the nature of the gating mechanisms that control the flow of ions across the membrane at the neuromuscular junction.*

TWENTY-FIVE years ago this year Hodgkin and Huxley published a series of papers that have served as the basis for virtually all succeeding studies on the mechanism of the nerve impulse<sup>1,2</sup>. The key idea in their analysis is that the permeability of the nerve membrane to certain specific ions, such as Na and K, is controlled by the voltage difference across the membrane. Cells expend metabolic energy to keep the concentrations of the various ions within the cell different from the concentrations in the outside bathing medium—for example, the intracellular concentration of Na is about an order of magnitude lower than it is in the extracellular fluid bathing the cell—and Hodgkin and Huxley showed that the electrical signs of the nerve impulse are accounted for by the permeability changes to these ions, and the resultant ionic rush toward equilibrium. To understand the molecular basis for nervous activity, then, we must penetrate the mechanism by which cell membranes change their permeability to ions.

Despite considerable progress in our understanding of neuronal mechanisms in the past 25 years, we still do not know precisely how, at the molecular level, membranes can alter their ionic permeabilities. Quite recently—during the past five years—several new approaches to this problem have been developed, and the expectation of their success has given rise to an optimism in the field that we may soon discover the molecular basis for the nerve impulse. My goal in this review is to describe one such approach, fluctuation analysis.

The idea behind fluctuation analysis is to exploit the inherently probabilistic nature of the processes that underlie the membrane permeability changes in order to gain information about the molecular mechanisms responsible. The functioning of excitable membranes depends on the opening and closing of channels. Because these channels behave probabilistically, the exact number of open channels fluctuates around the average value. For example, if a membrane contains 1,000 independent channels, each of which has a probability of being open of 0.5, the average number of open channels will be 500. A particular membrane might actually have 490 open channels at one time, 514 at a later time, and 502 at a still later time. These fluctuations in the number of open channels are governed by the same physical processes responsible for all channel behaviour, so the study of the statistical structure of the fluctuations can give information about the underlying biophysical mechanisms. It turns out, in fact, that fluctuations can sometimes contain information that is inaccessible by other practical techniques. I shall try here to explain, in largely non-mathematical terms, how fluctuation analysis has been used to increase our understanding of membrane per-

meability mechanisms, and shall indicate how the technique can contribute in future studies. Additional information on this subject can be found in a non-mathematical survey<sup>3</sup>, and in several more technical review articles that have appeared recently<sup>4-6</sup>.

My explanations about fluctuation analysis will be chiefly in the form of specific examples, first drawn from investigations of synaptic channels that are caused to open by the neurotransmitter acetylcholine, and second from the nerve membrane itself. Before giving these examples, however, I shall review briefly current views about the molecular basis for the nerve impulse, and survey some standard techniques for characterising fluctuations.

### Channels and gates

Changes in permeability to ions are responsible for the nerve impulse. How do these changes occur? The current view is that nerve cells have intrinsic membrane proteins that control the permeability to specific ions by providing channels through which they can pass. Each channel type is named for the ion that normally best passes through it, so one speaks of "sodium channels" and "potassium channels", even though potassium ions can move, for instance, through "sodium channels" to some extent.

Understanding how these membrane proteins regulate permeability to ions depends on the answers to two central questions. The first is: what are the molecular mechanisms responsible for the selective permeability of channels? For example, what is the physical basis for an ion-channel interaction that permits potassium ions (crystal radius = 1.33 Å) to pass through and nearly excludes sodium ions (crystal radius = 0.99 Å). The second central question relates to mechanisms by which membrane proteins alter ionic permeability. How, for example, is a membrane able to increase its permeability to sodium ions by many orders of magnitude in less than a millisecond? Questions of this second sort are said to deal with channel "gating", because increases in permeability occur as if gates obstructing the flow of ions through channels suddenly opened. This review is concerned primarily with gating rather than with selectivity.

Over the years since Hodgkin and Huxley first studied gating of sodium and potassium channels in the squid giant axon considerable information about this process has accumulated. There is now general agreement that gating occurs by conformational changes in a macromolecule. These conformational changes are driven principally by interactions of the gate with the membrane electric field (membrane field strengths change by about 100 kV cm<sup>-1</sup> during the nerve impulse) in electrically excitable membranes such as those of nerve cells, or by the binding of a ligand known as a neurotransmitter in chemically activated membranes such as those that occur at synapses. Ultimate

\*Department of Physiology, Yale University School of Medicine, 333 Cedar Street, New Haven, Connecticut 06510

understanding of gating would then involve knowing how electric fields or ligands can induce conformational transitions, knowing the number of possible conformational states the gate can assume and the rates of transition between these states, and finally relating this information to the structure of the gating macromolecule.

One of the main approaches to understanding the behaviour of gates is through the study of kinetics. This approach was instituted by Hodgkin and Huxley and involves measuring the rates at which channels go from the open to the closed state in various circumstances. For example, one might drive channels from the closed to the open state by causing a step-like change in the voltage across the nerve membrane. The time course of opening would be monitored by measuring the permeability of the membrane to, say, sodium ions as a function of time after the voltage step. One then tries to make inferences about the nature of the underlying conformational changes from the kinetics of channel opening revealed in such an experiment. Usually, experiments measure only the average number of channels open as a function of time in the sort of experiment just described, but more recently membrane biophysicists have been studying the fluctuations around the mean number of open channels. Such fluctuations occur because channel opening and closing is a probabilistic process. Although the investigation of these fluctuations is merely a variation on the more usual kinetic analysis, additional information can sometimes be gained from the fluctuations. My purpose here is to indicate why this is so.

### The structure of noise

Records of a fluctuating quantity, such as the number of open channels, have a statistical structure, and information about a system can be inferred from the character of this structure. Before giving examples of uses of fluctuation analysis, then, I shall summarise briefly some standard characterisations of noise. The following discussion will usually assume that the systems under study are stationary. This means that the statistical properties of the fluctuations do not change with time over the course of a set of observations. For example, if the fluctuating quantity under study is the number of open channels, the exact number of channels open varies from instant to instant, but the average number open must stay fixed for the length of the sample; if the average number of channels open is  $1/2$  at the start of the observation period, an average of  $1/2$  must be open throughout the period.

The simplest characterisation of fluctuations is the variance, that is, the average of the squared deviations from the mean. The variance is a usual measure for the amplitude of fluctuations.

The variance indicates the overall magnitude of fluctuations, but gives no information about how rapidly they vary with time. Random signals can, however, differ dramatically in how fast the wiggles occur with, for example, one type of system producing a signal dominated by low frequency fluctuations and another by higher frequencies. Much of the information about a system that can be extracted from its fluctuations is contained in this frequency structure. A natural way to extend the simple characterisation by variance to give information about the rapidity of fluctuations is to find the contribution that each frequency component of a random signal makes to the overall variance. A record of fluctuations could be decomposed by Fourier analysis into its various frequency components (for example, 1 Hz, 2 Hz, 3 Hz, . . . . ., 100 Hz), and the variance per Hertz contributed by each component could be computed. If the random signal generated by the system were slowly varying, the variance contributed by the higher frequencies would be small, whereas a rapidly changing signal would have a much larger contribution from the high frequency components. The collection of numbers that specify the variance per Hertz for the different frequency components of a random signal is known as the spectrum associated with that signal. Figure 1 presents examples of two experimentally determined spectra displayed in the usual double logarithmic plots.

The individual record of fluctuations produced by a probabilistic system is almost never exactly the same twice, but the

**Fig. 1** Sample fluctuations, and spectra from nerve and synaptic membranes. *a*, Fluctuations in potassium current and mean potassium current (proportional to potassium conductance) from a voltage-clamped frog node of Ranvier (T. Begenisch and C.F.S., unpublished observations). Lower trace is mean current through potassium channels as a function of time, with the potassium conductance activated by a positive going voltage step. Upper trace is simultaneous recording at  $40\times$  greater gain with the mean current subtracted out. Fluctuations on the left of the upper trace represent equipment noise contributions. Fluctuations due to channel opening and closing are visible on right of trace after the period of flat base line which represents a blanking pulse to suppress filter transients. *b*, Spectrum of frog node of Ranvier potassium current fluctuations such as those in *a* (from T. Begenisch and C.F.S., unpublished observations). *c*, Spectrum of fluctuations in current through acetylcholine activated channels at the frog nerve-muscle junction (C. Lewis and C.F.S., unpublished observations). Acetylcholine was iontophoretically applied to a voltage clamped post-junctional membrane, and the resulting current fluctuations (proportional to conductance fluctuations) Fourier analysed to give the spectral densities as a function of frequency plotted above.

spectrum characterising the fluctuations is, except for sampling errors, always just the same. This spectrum reflects the characteristic times of the underlying molecular processes, and in fact the reason for determining a spectrum is that it gives a way of measuring these characteristic times. If underlying processes are fast, the spectrum will reveal large contributions from high frequencies, and if the system is sluggish, only low frequencies will be appreciable.

Probability theory provides standard recipes for calculating what spectrum any underlying probabilistic mechanism will produce<sup>7,8</sup>. If one can formulate a probabilistic theory for a process, that theory provides predictions not only about the system's average behaviour, but also about the spectrum associated with the fluctuations about this average. Comparing predicted spectra with observed ones thus provides a way of testing for the accuracy of some proposed mechanism. It is extremely important to emphasise that no automatic way exists for using a spectrum to gain information about a system. The study of fluctuations can, as will be explained later, give information that might otherwise be inaccessible for practical reasons, but all inferences depend entirely on some sort of theory about the source of the fluctuations.

### Synapse channels

Fluctuation analysis has been most extensively used to study the permeability changes produced by the application of the neurotransmitter acetylcholine to postsynaptic membranes, and this system will thus be used for the first examples. Although the examples presented here do not by any means include all of the applications of this technique, they do illustrate types of use. Application of fluctuation analysis to postsynaptic membranes has recently been reviewed<sup>6</sup>.

When a nerve impulse reaches a synaptic nerve terminal on a muscle it causes the release of acetylcholine from the nerve ending. The acetylcholine diffuses to a specialised postjunctional region of the muscle membrane where it causes a transient permeability increase to sodium and some other ions. The permeability to these ions increases very rapidly and then decreases again over a several millisecond period. These permeability changes are the first step in a sequence that leads to muscle contraction, and they can be measured by recording the currents that flow through the muscle membrane. These currents that reflect the permeability increase caused by acetylcholine are called endplate currents.

Until fairly recently, workers in the field had generally believed that the endplate current was a fairly faithful representation of the time course of acetylcholine concentration at the postjunctional membrane. Acetylcholine is removed from the vicinity of the postjunctional membrane by diffusion and enzyme action, and the assumption had been that it took several milliseconds for the acetylcholine to disappear by these processes and that endplate current continued to flow for as long as the acetylcholine was present. An analysis of the acetylcholine-produced permeability increase at the frog neuromuscular junction led Magleby and Stevens<sup>9</sup> to propose a theory that supposed the rate limiting step in channel closing is a conformational change in the gating molecule rather than a decline in acetylcholine concentration. According to this theory, one must assume that acetylcholine remains near the postjunctional membrane only for a very short time. During the brief action of acetylcholine, channels open and then close probabilistically over a several-millisecond period after the acetylcholine has been removed. This theory accounts quantitatively for many properties of the endplate current, but the assumption that the channel-closing conformational change is rate limiting could not be put to direct test with the techniques available. The difficulty was that the acetylcholine concentration at the postjunctional membrane could not be rapidly measured or controlled. This difficulty was circumvented by using fluctuation analysis.

Katz and Miledi had discovered that sizeable fluctuations in muscle membrane permeability occur when a constant concentration of acetylcholine is present at the neuromuscular

junction, and they concluded that these fluctuations represent the random opening and closing of channels<sup>10</sup>. The scheme Magleby and Stevens developed to describe how acetylcholine causes permeability increases, being inherently a probabilistic theory, predicted the spectrum of these fluctuations. Specifically, channels were assumed to have just two conductance states, open and closed, and a channel was viewed as fluctuating randomly between these two states when acetylcholine was bound to a specific receptor associated with the channel. This theory predicts<sup>9</sup> that the spectral density  $S(f)$  (contribution to the total variance) of the component of fluctuations with frequency  $f$  should be given by

$$S(f) = \frac{4\gamma g/\alpha}{1 + (f/2\pi\alpha)^2} \quad (1)$$

where  $g$  is the average conductance increase caused by acetylcholine,  $\alpha$  is the average rate at which open channels make the transition to the closed state, and  $\gamma$  is the conductance of a single open channel. The average conductance can be measured in the same experiment that produces records of fluctuations, and  $\alpha$  can be obtained through the Magleby-Stevens theory, independently of the fluctuation measurements, from endplate currents produced by nerve stimulation. The only parameter in this equation not found independently was the single channel conductance  $\gamma$ , and this was known to have an approximately constant value under a variety of experimental conditions that produced quite large changes in  $\alpha$  and  $g$ .

The strategy then is to observe the conductance (that is, effectively permeability) fluctuations and calculate their spectrum. If the theory is correct, equation (1) should describe the spectrum accurately with only one constant  $\gamma$  to be estimated from the fluctuations. As various conditions are changed that alter the spectra,  $\gamma$  should remain constant. If the channel closing step is not rate limiting, or if the theory is incorrect in a number of other ways, equation (1) should not accurately characterise the experimentally determined spectra under the various different experimental conditions.

Using this approach, Anderson and Stevens<sup>11</sup> found that equation (1) was indeed an accurate description of the spectra. This success of the theory gave strong support to the idea that channel gating properties, rather than loss of acetylcholine from the nerve-muscle junction region, are rate limiting during the normal endplate current. Furthermore, once the theoretical interpretation of the source for fluctuations could be accepted, these same experiments gave a measurement of  $\gamma$ , the single channel conductance.

Two properties of individual channels may thus be estimated from fluctuations in permeability through the use of equation (1), the single channel conductance  $\gamma$  and the average closing rate for open channels  $\alpha$ . The statistical theory that led to equation (1) provides some additional information about the channel behaviour: the average length of time  $\tau$  that a channel, once open, remains open is just  $1/\alpha$ . Fluctuation analysis therefore gives a way of measuring the conductance of a channel, and the mean length of time it stays open without ever actually making measurements on a single channel.

Generally various inevitable sources of instrumentation noise make it impossible to record directly, and in isolation, single channel currents. By carefully analysing the sources of noise in current measurements and cleverly designing apparatus that minimises these noise contributions, however, Neher and Sakmann<sup>12</sup> have recently been able to record the currents flowing through individual acetylcholine-activated channels in frog postjunctional membrane. Their results are in accord with the picture developed on the basis of fluctuation analysis: channels seem to have only two conductance states (open and closed), and the duration of the open state is exponentially distributed. The mean open time and  $\gamma$  have values in agreement with those determined by investigation of fluctuations arising from many channels independently opening and closing. Neher's and Sakmann's achievement is particularly important because cer-

tain assumptions made in the theory on which fluctuation analysis is based could not be independently checked. For example, all of the data obtained before their direct demonstration of simple open-closed behaviour were equally consistent with the idea that a channel opened instantaneously and then decreased its conductance exponentially with time.

Fluctuation analysis has been used to answer a number of questions about acetylcholine-activated channels<sup>6</sup>. In some instances, the quantities of interest were single channel conductance or mean open time and equation (1) had to be used to estimate these quantities because they could not be found by alternative means. In other instances certain experimental manipulations led to more complicated situations in which the spectra had a more complex form than equation (1) and an equation for the spectral density had to be derived from an analysis of mechanisms. I will give two specific examples that illustrate these approaches.

Colquhoun *et al.*<sup>13</sup> have recently used fluctuation analysis as an aid in studying acetylcholine metabolism at the rat nerve-muscle junction. Their approach depends upon the important discovery by Katz and Miledi<sup>14</sup> that various analogues of the natural neurotransmitter acetylcholine each cause the channel to remain open for a different mean time for a given set of conditions. For example, the mean open time is shorter for carbacol than for acetylcholine, and longer for suberyldicholine than for acetylcholine. Colquhoun *et al.* found conditions under which monoethylcholine would be taken up by the nerve terminal and synthesised into acetylmonoethylcholine. This "false" neurotransmitter was then released by the nerve on stimulation. The fact that acetylmonoethylcholine was being released could be detected because channels stayed open a shorter average time with this false transmitter than with the normal acetylcholine, and the false transmitter was less potent than the normal one. The characteristic channel behaviour elicited by the false transmitter was found by using fluctuation analysis to measure channel mean open time and single channel conductance for externally applied acetylmonoethylcholine. Being able to detect the quantity of false and natural transmitter released means one can study the details of vesicle filling with more precision than otherwise possible.

Ruff<sup>15</sup> has recently used fluctuation analysis to help unravel the action of local anaesthetics at the postjunctional membrane. Normally the endplate current decays according to a simple exponential time course (reflecting the conformational change in closing) but, after treatment with local anaesthetics, the decaying phase of the endplate current exhibits two main exponentials, one faster and one slower than normal. Of the various hypotheses that could account quantitatively for this behaviour, two specific ones were: (1) the local anaesthetic molecules alter the lipid microenvironment of receptors and cause islands of lipid and proteins with two different characteristics. Some islands are stiffer than normal, whereas others are more fluid. In the more fluid islands, the conformational change can occur more rapidly (this gives the rapid exponential decay), whereas the stiffer environment produces slower than normal conformational changes (this gives the slower exponential component in the decay of endplate current). (2) Local anaesthetic molecules could rush in and block open channels so that ion transport through the membrane could not proceed but nor could the conformational change occur that closes the gate. In this theory the rapid exponential in the decay would reflect the initial establishment of a steady state number of blocked channels, and the second exponential would arise from the slow unblocking and closing step.

Both of these theories, as well as others, could account quantitatively for the decay of endplate currents and no observation on mean endplate currents can distinguish between them because they give rise to the same descriptive equation. The theories do, however, make different predictions about the spectra. Both mechanisms would give a spectrum with two components that is more complicated than the type described by equation (1). The amplitudes of the components are different for the two theories, so that a measurement of the mean endplate current and the spectrum permits a differential test. Ruff has carried out this procedure for the two theories indicated above

and others, and has found that the blocking mechanism is in quantitative agreement with the experimental observations, but predictions of alternative theories are not. This example illustrates a fairly common occurrence: different molecular mechanisms make identical or practically indistinguishable predictions about average behaviour, but give rise to spectra with easily detectable differences.

## Nerve channels

In 1966 Verveen and Derksen published a short account of their studies on fluctuations in nerve membrane permeability<sup>16</sup> and thus began the use of fluctuation analysis to investigate nerve membrane properties. Interestingly, the main motivation for the early studies from Verveen's laboratory related more to information processing properties of the neurones than to the molecular mechanisms of excitability. Verveen's thesis<sup>17</sup> had been concerned with random threshold fluctuations in nerve, and he and Derksen had set out to discover the membrane correlates of this phenomenon. Blair and Erlanger<sup>18</sup> had, in the course of their pioneering work on the nerve impulse, discovered that nerves stimulated near threshold produce nerve impulses probabilistically, and Pecher<sup>19</sup> had quite carefully investigated this phenomenon and found that the threshold variations were independent and normally distributed if stimuli were applied at an appropriate rate. Early interest thus centred on the probabilistic behaviour neurones exhibited in some circumstances, and was largely motivated by implications this behaviour has for nervous system function: how can the nervous system be reliable when its basic elements, the neurones, are "unreliable" in the sense that they cannot be counted on to give a nerve impulse whenever stimulated?

In recent years, however, the main motivation for the study of fluctuations in properties of the nerve membrane has been related not to information processing, but rather to the significance for the molecular basis of nerve excitability. Furthermore primary interest has shifted from studies of the so called "1/f noise" first described by Verveen and Derksen to the conductance fluctuations that arise from the probabilistic opening and closing of channels. In the remainder of this review I shall concentrate on "channel noise" rather than on the 1/f noise associated with ion motion through open channels; that is, my attention will be limited to fluctuations in conductance associated with the opening and closing of the channels responsible for nerve excitability.

A resting nerve cell normally has an interior that is about 60 mV more negative than the outside solution. If the voltage across the cell membrane is displaced from the normal resting value of -60 mV to more positive values, ion selective channels (Na, K, Ca) are caused to open so that the membrane conductance increases. Hodgkin and Huxley discovered that the increase in conductance as a function of voltage is a sigmoid function of voltage for each channel type (Fig. 2).

Two limiting mechanisms can be envisaged for this type of behaviour. On the one hand, one could suppose that each channel opened in a graded manner with voltage. According to this view, we might expect that, if the conductance of just one channel could be measured at different voltages, a single channel would show a conductance against voltage plot like that exhibited in Fig. 2. On the other hand, each channel might have only two conductance states, open and closed, and the gross conductance against voltage curve (Fig. 2) might simply reflect the fraction of channels open at any voltage. Of course, intermediate cases are easily envisaged. A channel might have, say, four different conductance levels (closed, 1/3 open, 2/3 open, fully open), and Fig. 2 would reflect the fraction of channels in each of their conductance states. Clearly, one cannot formulate a theory for channel opening mechanisms without knowing which of these possibilities is correct. Fluctuation analysis has been used to investigate this important question, and is, unfortunately, the only approach currently available.

At the acetylcholine-activated channels of the nerve-muscle junction increasing the dose of acetylcholine causes a larger conductance by causing more channels to open, but  $\gamma$  has the

**Fig. 2** A typical plot of steady-state conductance for one channel type (potassium, for example) as a function of voltage difference between the interior of a nerve cell and the exterior solution. The ordinate presents conductance as a fraction of the maximum possible value.

same value irrespective of how many channels are opened on the average. For the nerve membrane, channels open in response to the membrane voltage rather than the presence of a neurotransmitter like acetylcholine, but in this case as well,  $\gamma$  should be independent of the number of open channels if each channel has only two conductance states, open and closed. If, on the other hand, each channel has many conductance states, with the higher conductances favoured by positive voltages, one might expect that  $\gamma$  would increase as the total conductance were increased by subjecting the membrane to positive voltages. Although the actual situation turns out to be somewhat more complicated than these simplest expectations, fluctuation analysis can show whether  $\gamma$  remains constant as the total conductance increases.

The use of fluctuation analysis to get an indication of how many conductance states a type of channel might have is best introduced by considering the limiting case in which channels can be only open and closed. According to simple coin-flipping theory<sup>7,8</sup>, we know that the average conductance is

$$g = \gamma Nf \quad (2)$$

where  $\gamma$  is the single channel conductance,  $g$  is the average total membrane conductance,  $N$  is the number of channels in the membrane (they are assumed to be independent), and  $f$  is the probability that a channel is open. The quantity  $f$  would depend on voltage, and thus so would  $g$ . The variance in conductance is

$$s^2 = \gamma^2 Nf(1-f); \quad (3)$$

where  $s^2$  is the variance and other symbols have the same meaning as in equation (2). The quantities  $g$  and  $s^2$  can be measured in experiment, and  $f$  can be estimated from the conductance/voltage function such as appears in Fig. 2 if we assume that maximum conductance corresponds to a channel certainly being open ( $f$  is then just the fraction of the maximum conductance). Eliminating the unknown quantity  $N$  from equations (2) and (3), we can solve for  $\gamma$ , the single channel conductance, in terms of measurable quantities  $g$ ,  $s^2$ , and  $f$ :

$$\gamma = \frac{s^2}{g(1-f)} \quad (4)$$

Equation (4) gives a means of estimating single channel conductance if channels have only two conductance states.

If the excitable membrane channels have only two conductance states then  $\gamma$  estimated by equation (4) should, like the acetylcholine-activated channels described earlier, always have the same value. (Actually channels show rectification under some circumstances, so  $\gamma$  might appear non-constant. This rectification can be taken into account by measuring the instantaneous voltage-current relation and using the information to refer values of  $\gamma$  to some reference voltage.) As the membrane voltage is made more positive the probability that a channel is open approaches unity; the average number of open channels thus increases with positive voltages, so the average conductance  $g$  might increase along a sigmoid curve like that illustrated in Fig. 2. The variance in conductance fluctuations should, however, follow an inverted U-shaped function of voltage (according to equation (3)) that gives a constant  $\gamma$  estimate.

What would be expected if single channels have multiple conductance states so that the average conductance of a channel increases as the membrane voltage is made more positive? In general,  $\gamma$  as defined by equation (4) would not for this case be a constant independent of membrane voltage, but the exact behaviour of  $\gamma$  as the total conductance increased would depend on the exact mechanism underlying the conductance increase. Specifically,  $\gamma$  (according to equations (4)) might increase, decrease, or remain constant as  $g$  was increased by making the membrane voltage more positive. If the primary means by which the membrane increases its overall conductance is by making each channel more conductive,  $\gamma$  would, on the simplest theories, increase as  $g$  did. It is not difficult, however, to construct specific examples in which  $\gamma$  remains constant or decreases as  $g$  is increased.

In summary, measuring  $\gamma$  as a function of the mean conductance  $g$  can give an indication about whether individual channels have two or more than two conductance states. If a channel can only be open and closed,  $\gamma$  must be constant. If  $\gamma$  calculated from equation (4) is actually observed to be constant, the simplest interpretation is that channels can be only open or closed. The experiments performed so far indicate that  $\gamma$  is constant as  $g$  increases, so gates seem to behave in the simple open-closed way.

Three investigations of single channel conductance, estimated by equation (4), as a function of the total conductance  $g$  have appeared, all on frog nerve; one study was on potassium channels<sup>20</sup>, and two on sodium channels<sup>21,22</sup>. Begenisich and Stevens<sup>20</sup> could find no significant change in  $\gamma$  for K channels over a range of voltages that give from 15% to 85% of the maximum conductance. These workers found that the single channel conductance was 4 pS ( $4 \times 10^{-12}$  ohm<sup>-1</sup>), a value about 7 times lower than that for the acetylcholine-activated channels.

Sodium channels are more difficult to investigate than are potassium channels because of sodium channel inactivation: at most voltages, sodium channels open only transiently. The opening process is called activation and the closing, in the face of a maintained positive voltage, is known as inactivation. For example, if the membrane voltage is changed from a resting value of -60 mV to +40 mV, the sodium conductance would rapidly increase, and then decrease to nearly zero even though the voltage was kept constant. After becoming inactivated, sodium channels must have a rest period at a negative voltage before they can be activated again. This process of inactivation not only complicates the theoretical analysis of sodium channels, but also hinders the application of fluctuation analysis that requires observation to be made during a relatively long period during which the average conductance remains nearly constant. Potassium channels also show a similar inactivation phenomenon, but the rate of development of the inactivated state is so slow that sufficiently long samples with an insignificant change in mean conductance can be obtained.

Conti *et al.*<sup>22</sup> have studied fluctuations to investigate the behaviour of the sodium channel  $\gamma$  as the average conductance was varied. Because of the presence of sodium channel inactivation, however, these workers were restricted to a somewhat smaller range of voltages than were Begenisich and Stevens. As

with the potassium channel,  $\gamma$  remained constant over the entire accessible voltage range with a value of about 8 pS.

More recently Sigworth<sup>22</sup> has approached the problem with a different method that does not assume stationarity and that therefore circumvents the difficulties arising from the presence of sodium channel inactivation. The studies described until now have all carried out an analysis of fluctuations that occur over time around a constant or nearly constant mean value. Sigworth collected an ensemble of records with a transient rise and fall in sodium conductance. These records should all have been identical except for probabilistic fluctuations. After evaluating the source of variability other than from the random opening and closing of channels, Sigworth calculated the variance about the mean from all records at each time point. Equation (4) should still hold, except that the mean and variance are calculated for an ensemble of records rather than over time for a single record.

Using this approach, Sigworth was able to estimate  $\gamma$  over the entire range from the resting voltage to +150 mV. In confirmation of the findings of Conti *et al.*, these experiments give a constant  $\gamma$  with a value of 8 pS under normal conditions. The value of  $\gamma$  was unchanged by treatment with tetrodotoxin, agent that decreases the number of functional channels present, but was decreased by lowering pH. This pH effect is consistent with a blocking action of hydrogen ions on ionic conduction through the channel<sup>23</sup>.

Although these studies are certainly not conclusive, they do constitute the first experimental support for the notion that channels in the nerve membrane, like the acetylcholine-activated channels at the nerve-muscle junction, have only two main conductance states, open and closed. If sustained by future research, this conclusion greatly simplifies the understanding of gating mechanisms.

The first application, of fluctuation analysis to nerve membrane, thus relates to evidence for an all-or-none gate on potassium and sodium channels. Another use, and one that will probably be more important, is in distinguishing between various possible molecular mechanisms of gating. Even at a constant voltage, the time course by which nerve channels open and close is quite complicated and requires a fairly high order differential equation for a good description. The Hodgkin-Huxley equations for potassium channels, for example, involve a fourth order differential equation. The difficulty is that various possible underlying mechanisms can give rise to the same equation for average behaviour, and an even larger number of mechanisms is consistent with similar mathematical descriptions that would, in

practice, be indistinguishable in their predictions for average behaviour. In general, however, distinct molecular mechanisms that predict identical or very similar average behaviour can make quite different predictions about the spectra of conductance fluctuations. Fluctuation analysis, then, has the potential of helping to decide between various alternative mechanisms that equally well account for the average behaviour of nerve channels. This approach has already been successfully used by Ruff, as described earlier, in investigations of local anaesthetic actions.

A number of investigators have published spectra of conductance fluctuations for nerve membranes<sup>21,24-29</sup>. So far, however, for reasons that are not yet clear, no two laboratories have managed to agree on the form and amplitudes of the spectra they find. The nature of these disagreements has recently been detailed by Nether and Stevens<sup>6</sup> and will not be repeated here.

To summarise, one may say that fluctuation analysis has already helped in understanding gating mechanisms at the nerve-muscle junction as indicated by the examples given earlier. Further the technique has given the first experimental evidence that nerve channels gates behave in all all-or-none manner. The challenge for the future will be to make use of this approach to elucidate the processes underlying the phenomena described by the Hodgkin-Huxley equations.

## Hubble's constant determined from super-luminal radio sources

D. Lynden-Bell

Institute of Astronomy, The Observatories, Cambridge, UK

*Recent data on the so-called super-light expansion velocities observed in the radio galaxy 3C120 show a good fit to the light echo theory, provided the Hubble constant is  $110 \pm 10 \text{ km s}^{-1} \text{ Mpc}^{-1}$ . Statistics on three super-luminal sources interpreted with that theory give the same Hubble constant. A method of determining  $q_0$  from each source with data that may already exist, looks very promising.*

REES and others<sup>1,2</sup> have displayed remarkable ingenuity in devising mechanisms that can lead to high multiples of  $c$  in apparent transverse motion, nevertheless, the only theory that looks plausible for general application is the old 'light echo' theory<sup>3</sup>. In 1901 Nova Persei exploded close to a reflection nebula and its light echo was seen on the nebula with an apparent transverse expansion of a diameter of  $2c$ , and was used to determine a distance to Nova Persei<sup>4</sup>. I aim to show here that the

mystery that surrounds the super-luminal velocities observed in radio sources is a myth, and that all well observed objects can be explained with this old theory. The mystery has developed because most authors preferred too low a value of the Hubble constant and the interpretation of the data has caused some confusion. This investigation was stimulated by the account of Cohen *et al.*<sup>5</sup> of both super-luminal velocities and the ambiguities of their interpretation.

My accretion disk picture<sup>6</sup> of quasars and Seyfert galaxies<sup>7-10</sup> has the inner part of the disk inflated into a nearly spherical shape by radiation pressure<sup>10,11</sup>. Just as water flowing into the black hole in a bath does so around a narrow vortex, so the sphere is pierced by a narrow vortex hole on the sides of which velocities close to  $c$  are reached as the central black hole is approached. X rays, strong electromagnetic waves and relativistic plasma generated close to the hole can only escape up or down the narrow tube formed by this vortex. I shall assume that brilliant flashes of radiation (or alternatively relativistic shock waves moving with velocity  $c$ ) emerge up these oppositely-directed holes and that their energy density is so great that they generate relativistic random motions in the plasma they illuminate. This causes the plasma to radiate by the synchrotron process. The patches illuminated by a flash from the centre each move out with the velocity of light. If the tube were perpendicular to the line of sight the apparent transverse expansion apart of the two components would be  $2c$ . Allowance for an angle  $\theta$  between the tube and the observers's line of sight, however, changes this to  $2c/\sin \theta$ .

There are two immediate objections to this theory. (1) 3C120 has shown two flashes at  $5c$  and  $8c$  so that  $\theta$  must change over a short period, but the position angle on the sky remains unchanged. I shall show that the second expansion velocity is caused by a misinterpretation and that the events in this galaxy fit the theory perfectly. (2) There are too many very large multiples of  $c$  observed in apparent expansions. This is explained by the change of Hubble constant together with some over-concentration on more esoteric interpretations of observed events. In particular Cohen *et al.*<sup>5</sup> point out that events in 3C279 can either be interpreted as a  $10c$  expansion ( $5c$  on the new Hubble constant) or as three fixed sources of variable intensity. No doubt two moving sources and an off-central source of variability would be as good.

The light echo theory used here suggests rules of interpretation which should help to build much better models from very long baseline (VLB) data. These in turn will yield values for  $q_0$  the deceleration parameter that determines the geometry of the universe. Data probably already exist which will allow this to be done for 3C345, 3C279, 3C454.3.

Here a simple account of the light echo theory and its predictions is given. These are used to determine the Hubble constant in two different ways. First, from the data on 3C120 and second, from the statistics of the three well-observed super-luminal expansions.

### Simple light echo theory for non-cosmological distances

Consider an object O not moving with respect to the radio antenna A. Let its tube point at  $\theta$  to the line of sight. Then a flash from O will illuminate and excite material at a source  $S_1$  distant  $ct$  from it. This event will be seen by A not at time  $t$  after he sees the initial burst at O but at time  $t - (ct \cos \theta)/c$  because the source  $S_1$  is nearer than O. The observed transverse velocity of  $S_1$  is

$$[ct \sin \theta]/[t(1 - \cos \theta)].$$

That is

$$v_1/c = \sin \theta / (1 - \cos \theta) \quad (1)$$

The source flying in the opposite direction has apparent transverse motion  $v_2$  where

$$v_2/c = \sin \theta / (1 + \cos \theta) \quad (2)$$

The apparent separation velocity is the sum of these

$$v_s = 2c \sin \theta / (1 - \cos^2 \theta) = 2c / \sin \theta \quad (3)$$

Note that the apparent velocity of separation can not be  $< 2c$ . Also if  $S_1$ ,  $S_2$  and O are all seen, then the separation ratio

$$\frac{S_1 O}{S_2 O} = \frac{1 + \cos \theta}{1 - \cos \theta} \quad (4)$$

and so  $\theta$  can be determined direct from such observations. With  $\theta$  known and the apparent angular separation rate  $\dot{\chi} = v_s/D$  found from VLB observation then the distance  $D$  is  $v_s/\dot{\chi} = 2c(\dot{\chi} \sin \theta)^{-1}$ . The Hubble constant is then determined from the redshift  $z$  of the object at O by  $H_0 = cz/D$ .

### Modification factors

The above theory is subject to simple modification when the object O is not observed at rest but nearby at a large redshift  $z$ . In the first case the observer allowing for time dilation attributes an 'apparent' expansion velocity  $v_s$  related to  $\dot{\chi}$  by  $\dot{\chi} = v_s/[D(1+z)]$ . The events seem to happen slower than they really do because of the redshift. Second, the great time lapse between the emission and the reception of the radiation is large and the geometry may not be Euclidean or Minkowskian. In particular in Friedmann universes the formula connecting the apparent transverse motion  $\dot{\chi}$  and  $v_s$  is not

$$v_s = D\dot{\chi}(1+z) \doteq \frac{cz}{H_0}(1+z)\dot{\chi} \quad (5)$$

where  $H_0$  is the Hubble constant, but is modified by factors dependent on the acceleration parameter  $q_0$ . The full formula (given in ref. 5) is

$$\frac{v_s}{c} = \frac{\dot{\chi}}{H_0} q_0^{-2} (1+z)^{-1} \{q_0 z - (1-q_0)[(1+2q_0 z)^{1/2} - 1]\} \quad (6)$$

for  $q_0 z \ll \frac{1}{2}$  this gives

$$\frac{v_s}{c} = \frac{z}{H_0} (1+z)^{-1} [1 + \frac{1}{2}(1-q_0)z] \quad (7)$$

Note the correction factor of  $(1+z)^{-2} [1 + \frac{1}{2}(1-q_0)z]$  as compared with the simple equation (5). Equation (4) being a ratio of separations still holds good as do equations for  $v_1/v_s$  and  $v_2/v_s$  obtained by dividing equation (1) by (3) and equation (2) by (3).

Fig. 1 A flash at O in a tube illuminates and excites two patches of plasma seen by the antenna A at positions  $S_1$  and  $S_2$ . Whereas both  $S_1$  and  $S_2$  actually travel out at the speed of light,  $S_2$  is seen at an earlier source epoch because it is further away.

Fig. 2 The observations of 3C120 as reported in ref. 5 but with a dotted line superposed. *b*, plots  $\chi$  the separation angle  $S_1AS_2$  against time.  $\bullet$ , 2.8 cm;  $\circ$ , 3.8 cm;  $\blacktriangle$ , 6.0 cm. *a*, The 3.8 cm flux.

### Application to 3C120

Figure 2 shows the observations given in ref. (5). The 3.8-cm flux shows an outburst in 1973 which caused a double source. This was seen as a simple double expanding at about  $v_s = 5c$  (solid line) until 1974.2 when the double model failed to fit well, because of a small increase of flux. In 1975 there followed a violent increase of flux and immediately a two source model fitted well again, but at about the same separation as it was at 1974.0. The source began to dim in late 1975 and in 1976.1 it was again a well-determined double although the flux then was not given. Cohen *et al.* interpreted these events as the two super-luminal expansions of  $5c$  and  $8c$  given by the heavy straight lines. In my interpretation, however, this would involve the vortex tube up the rotation axis of the radio galaxy to turn between the two events and I consider this unlikely, especially as the observed position angle of separation on the sky are the same for both doubles. The following interpretation of events is more natural. 1972.5–1973 a double expanding source  $S_1, S_2$  was born at O and expanded throughout 1973 as its flux diminished. In early 1974, the object at O brightens, confusing the neat double interpretation of the data. In 1975.2, O has increased in brightness so much that it forms a double with  $S_1$ , the source moving towards the Earth and  $S_2$  is outshone and ignored. O dims in late 1975 leading to a confused picture with  $S_1, O$  and  $S_2$  all seen. Finally in 1976, O dies away leaving the old expanding source  $S_1 S_2$ . This latest point fits on the dotted expansion line ( $4.6c$ ) of the old source, which is a good alternative to the full line ( $5c$ ) if one ignores confused data. The importance of this new interpretation arises because it not only removes the discrepancy of two different super-luminal velocities observed from the same object, and therefore probably at the same  $\theta$  but, because we see O at times we can

measure the ratio of the separations  $OS_1$  to  $OS_2$  and hence determine  $\theta$ . Hence, the apparent transverse separation velocity is known from equation (3) so the observed angular velocity gives the distance and hence Hubble's constant. The small  $z = 0.033$  of 3C120 makes the cosmological corrections unimportant for this source, so the Hubble constant derived in this case is independent of  $q_0$ . The same method applied to 3C345 should also yield a good value of  $q_0$ .

If  $\theta$  were  $90^\circ$  the clear double seen in 1975.4 would have been half way up to the dotted line. Its fractional offset  $[OS_1 - \frac{1}{2}S_1S_2]/S_1S_2$  corresponds to the offset of O from the centre of  $S_1$  and  $S_2$  and is, therefore,  $\frac{1}{2} \cos \theta$ , from this  $\theta = 68^\circ \pm 10^\circ$ . It is particularly interesting that this angle is close to the inclination of the apparent disk of 3C120 measured from Arp's picture on which it seems to be a disturbed spiral<sup>12</sup>. From his picture,  $i = 55\text{--}60^\circ$  but this may be in error by  $10^\circ$  due to the fact that the disturbed disk does not have a circular outline. Furthermore the observed separation of the radio double, although fairly close to the apparent minor axis of the optical image is not along it. It seems reasonable to assume that ejection is taking place along the rotation axis, but the galaxy has imperfect circular symmetry. In such a case  $i$  should equal  $\theta$  and as both determinations have similar errors we shall take  $\theta = 64 \pm 8^\circ$ . The light echo theory then gives

$$v_s = 2c/\sin 64^\circ = 2.22c \pm 0.19c.$$

Cohen *et al.* adopt  $H_0 = 55 \text{ km s}^{-1} \text{ Mpc}^{-1}$  and obtained  $5c$  for this velocity, but our correction to the dotted line interpretation of Fig. 2 yields  $4.6c$  on that scale. To deduce the answer from the light echo theory the Hubble constant must be changed by  $(4.6 \pm 0.2)/(2.22 \pm 0.19) = 2.1 \pm 0.2$  producing Hubble constant of  $115 \pm 12 \text{ km s}^{-1} \text{ Mpc}^{-1}$ .

### Application to 3C273

Triple models have been given<sup>13</sup> for 3C273 and the best ratio of source distances from the centre gives  $\cos \theta = 0.2 \pm 0.2$ ,  $\theta = 78.5^\circ \pm 12^\circ$ . The expected expansion is  $2c/\sin \theta = 2.04c$  while the observations give  $4.2c$  on the  $H_0 = 55$  scale, with  $q_0 = 0.05$ . The correction factor is thus  $4.2/2.04 = 2.05$  yielding a Hubble constant of  $113^{+3}_{-10} \text{ km s}^{-1} \text{ Mpc}^{-1}$ .

### Statistics of super-luminal expansions

From equation (3)  $v_s = 2c/\sin \theta$  so this velocity cannot be less than  $2c$ . Furthermore most of the solid angle of a sphere is not too far from its equator, so  $v_s$  ought often to be just greater than  $2c$ , whereas  $v_s > 6c$  should occur only seldom. The times a super-luminal velocity less than some chosen  $v_s$  is seen should be

$$\frac{N(v_s)}{N_0} = (2\pi)^{-1}[(2\pi - 2\pi(1 - \cos \theta))] = \cos \theta = \left[1 - \left(\frac{2c}{v_s}\right)^2\right]^{1/2} \quad (8)$$

for  $v_s > 2c$  or for  $v_s < 2c$

The distribution function for  $v_s$  should be  $-d(N/N_0)/dv_s$  and this is plotted as Fig. 3. With only three well determined super-luminal velocities to consider, however, it is better to consider the formulae for the integrated distribution and its moments. In particular averaged over angle

$$\left\langle \frac{1}{v_s} \right\rangle = \int \frac{1}{v_s} \frac{dN}{N_0} = \frac{\pi}{8c} = \frac{0.79}{2c} \quad (9)$$

and

$$\sigma^2 = \left\langle \left( \frac{1}{v_s} - \left\langle \frac{1}{v_s} \right\rangle \right)^2 \right\rangle = \left( \frac{2}{3} - \frac{\pi^2}{16} \right) \frac{1}{4c^2} \quad (10)$$

$$\sigma = 0.22/2c.$$

The three well determined super-luminal velocities are, on the  $H_0 = 55 \text{ km s}^{-1} \text{ Mpc}^{-1}$  scale with  $q_0$  assumed small ( $q_0 = 0.05$ ),  $v_s/c = 4.6, 4.2$ , and  $7.0$  in the objects 3C120, 3C273 and 3C345 respectively. Thus with standard errors for the mean

$$\left\langle \frac{1}{v_s} \right\rangle = (0.20 \pm 0.05) \frac{1}{c} = (0.40 \pm 0.10) \frac{1}{2c}$$

To scale this to the theoretical value of equation (9) we must change

Fig. 3 a, The distribution of superluminal velocities expected from the light echo theory, and b, its integral plotted against  $2c/v_s$  compared with the histogram of observed data.

Hubble's constant by  $0.79/(0.4 \pm 0.1) = 2.0 \pm 0.5$  giving  $H_0 = 110 \pm 30$ . One further constraint on the factor may be independently deduced from the expansion of 3C273 at  $4.2c$  on the  $H_0 = 55$  scale. From our theory this must be greater than  $2c$  so the correction factor cannot be larger than 2.1. Taking this and its error into account the best value of the correction factor is  $2.0 \pm 0.1$  and the Hubble constant is  $110 \text{ km s}^{-1} \text{ Mpc}^{-1}$  with a maximum error upwards of  $10 \text{ km s}^{-1} \text{ Mpc}^{-1}$  and an r.m.s. error downwards of about 10 also.

Principles for interpreting super-luminal source data on light

echo theory are (1) Bursts occur at the source O. (2) They usually cause pairs of expanding sources  $S_1, S_2$  of which  $S_1$ , the one nearer the observer, is normally seen as the brighter. Since  $S_2$  is seen at an earlier source epoch it may have a flatter (harder) spectrum than  $S_1$ . (3)  $S_1$  and  $S_2$  expand outwards at velocities  $c \sin \theta / [1 - \cos \theta]$  and  $c \sin \theta / [1 + \cos \theta]$  respectively. These velocities do not accelerate. (4) Further bursts may occur at O leading to a brightening of O possibly followed by further source pairs  $S_1', S_2'$  travelling along the same position angle and at the same velocities as  $S_1$  and  $S_2$  respectively. (5) All source pairs will eventually fade but the source O is responsible for all very rapid time variability.

### Predictions

The light echo interpretation of the 3C120 data suggest that when the 3.8 cm flux at 1976.1 is disclosed it will again be low. Also that the next experiment will show a point on the dotted line of Fig. 2 if the flux continues low. It also suggests that the ratio  $S_2O/S_1O$  will be about 0.10 if O is seen in 3C345 (we may already have seen O and not  $S_2$  in which case we still expect the same ratio).

The new value of  $H_0$  predicts that no super-light velocities  $v_s$  less than  $4c$  on the old  $H_0 = 55$  scale will be detected. If, however,  $S_2$  were not seen the separation speeds of  $v_1$  down to  $2c$  on that old scale could be found. Finally each source should give the same value for  $H_0$  if this interpretation is correct.

### Conclusions

The Hubble constant is  $110 \pm 10 \text{ km s}^{-1} \text{ Mpc}^{-1}$ . The universe is half the linear size and half the age that would be attributed to it on the old Hubble constant of  $55 \text{ km s}^{-1} \text{ Mpc}^{-1}$ . The new  $H_0^{-1}$  age is  $9 \times 10^9$  yr and this means that Einstein-de Sitter age of  $\frac{2}{3}H_0^{-1}$  is embarrassingly small for stellar evolution theory. Hence, it is probable that the Universe is open with a small value of  $q_0$ . For many years Van den Bergh and de Vaucouleurs, and more recently Dibai, Hanes, Hartwick and Madore, have advocated almost as large values of the Hubble constant.

I thank the large VLBI teams for their hard work and J. R. Shakeshaft, D. Richstone and G. Wegner for helpful discussions.

## Optimum efficiency of photogalvanic cells for solar energy conversion

W. John Albery

Physical Chemistry Laboratory, South Parks Road, Oxford, UK

Mary D. Archer

Department of Physical Chemistry, Lensfield Road, Cambridge, UK

The performance of photogalvanic cells for the direct conversion of solar energy to electrical energy depends on the cell photochemistry, the homogeneous kinetics, the mass transport, the electrode kinetics and the load on the cell. The variation of the power output with the concentrations of the redox couples, their transport and kinetic parameters and the dimensions of the cell is found. The power conversion efficiency of the optimal cell could be as large as 18% but it is unlikely that all the necessary conditions can be met. A more realistic estimate of the maximum power conversion efficiency that could be achieved from a photogalvanic cell is between 5 and 9%.

PHOTO GALVANIC cells are possible devices for the direct conversion of solar energy into electrical energy. This paper is concerned with the maximum power that can be achieved by such devices and with describing the conditions for the most efficient operation of such cells. The cell works by the reactions

Two redox couples A,B and Y,Z are present in the solution; in the dark there is a very small concentration of B. On illumination, the absorption of radiation by A and the subsequent electron transfer reaction of A\* with Z generates B. The photogenerated B reacts on one of the electrodes thereby generating power. Examples of this type of system are shown in equations (2) and (3). We assume that the concentrations of Y and Z are large, compared to the concentration of A so that the concentrations of Y and Z throughout the cell are not significantly perturbed from their values in the dark.

where bpy = 2,2'-bipyridine.

The best geometry for the cell consists of two parallel electrodes separated by a thin layer ( $\sim 0.1$  mm) of electrolyte solution. One of the electrodes is transparent (such as  $\text{SnO}_2$ ); the light is shone through this electrode, as shown in Fig. 1.

### Reactions on electrodes

The performance of the cell depends first on the kinetics of the electrode reactions. On either electrode, either couple can have 'reversible' or 'irreversible' electrode kinetics. When a couple is reversible the electrode kinetics are rapid and the surface concentrations of the couple at the electrode obey the Nernst equation. When a couple is irreversible the electrode kinetics are sluggish and we only consider the extreme case where no electrode reaction takes place. The performance of cells, in which couples have intermediate electrode kinetics, will be between the two extremes that we consider. Four of the 16 possible cases are shown in Table 1.

Eight cases which have irreversible electrode kinetics for both couples on either of the electrodes can be rejected because to pass current it is essential that one of the couples should be reversible on each electrode. Four cases in which the Y,Z couple is reversible on both electrodes can be rejected because we have assumed that there is an insignificant perturbation to the concentrations of the Y,Z couple; so if the couple is reversible, the two electrodes will have the same potential and no power is produced. Similarly the fourth case of Table 1 can be rejected because at the dark electrode the reversible A,B couple will give the same potential as the reversible Y,Z couple at the illuminated electrode. This leaves three cases worth considering. In the first, the electrode kinetics are similar on the two electrodes and hence they can be made of the same material. The cell works as a 'concentration cell'. In the

other two cases the electrode kinetics are different on the two electrodes and the cell works with 'differential electrode kinetics'.

### Concentration of B in solution

To find the power developed by the cell we have to calculate how the concentration of B varies with the distance between the two electrodes. A steady state is established described by the differential equation (4)

$$D \frac{\partial^2 b}{\partial x^2} + \phi I \epsilon a - kby = 0 \quad (4)$$

where  $D$  is the diffusion coefficient of B;  $x$  describes the distance from the illuminated electrode;  $\phi$  is the quantum efficiency for the generation of B from A;  $I$  is the quantum intensity of the light;  $\epsilon$  is the natural extinction coefficient of A;  $a$ ,  $b$ , and  $y$  are the concentrations of A, B and Y respectively; and  $a_0$  is the concentration of A in the unilluminated solution.

The first term describes the diffusion of B, the second term its photochemical generation and the third term the thermal reaction with Y. There is no term describing transport by convection because we assume that the electrodes are close enough ( $< 0.1$  mm) for natural convection not to develop. There is no advantage in having the electrodes further apart and there may be the disadvantage that the internal resistance of the cell may be larger.

The light intensity in equation (4) varies with  $x$  and obeys

$$\frac{\partial I}{\partial x} = -\epsilon a I = -\epsilon(a_0 - b)I \quad (5)$$

where we have assumed that the diffusion coefficients of A and B are equal so that  $a + b = a_0$ . This differential equation gives the Beer-Lambert law when  $b \ll a_0$ , but we have also investigated the situation where  $b \approx a_0$  which means that the solution is bleached.

The boundary condition for equation (5) is that at  $x = 0$ ,  $I = I_0$ .

The boundary conditions for equation (4) depend on the electrode kinetics. At the illuminated electrode for the first three cases in Table 1

$$\left( \frac{\partial b}{\partial x} \right)_0 = b'_0 = \frac{|i|}{AFD} \quad (6)$$

At the dark electrode the boundary conditions depend on the different electrode kinetics shown in Table 1 and are: concentration cell,  $(\partial b / \partial x)_1 = b'_0$ ; differential electrode kinetics case I  $(\partial b / \partial x)_1 = 0$ ; case II  $b_1 \rightarrow 0$ .

The case II boundary condition arises because with both couples reversible, the dark electrode re-establishes at its surface

Table 1 Reversible (R) or irreversible (I) electrode kinetics

	Illuminated electrode		Dark electrode		Notes
	A,B	Y,Z	A,B	Y,Z	
Couple					
Case 1	R	I	R	I	Concentration cell
Case 2	R	I	I	R	Differential electrode kinetics I
Case 3	R	I	R	R	Differential electrode kinetics II

Fig. 1 Typical photogalvanic cell.

the equilibrium values of the concentrations found in the un-illuminated solution; any B is destroyed by the electrode:

The solution of the differential equations with the boundary conditions has been described elsewhere<sup>1,2</sup>. The value of  $b$  at the illuminated electrode allows the potential at that electrode to be calculated from the Nernst equation, as in all three cases the A,B couple is reversible. For the concentration cell a similar calculation is carried out at the dark electrode. For cells with differential electrode kinetics the potential difference at the dark electrode is unchanged from its value where the cell is un-illuminated. Hence for each value of the current using equation (6) we can calculate the potential difference across the cell and hence the power produced.

## Results

In giving the results of the calculations it is convenient to introduce the characteristic lengths given in Table 2. In Fig. 2 we show some typical concentration profiles for different values of the characteristic lengths and for the different electrode kinetics given in Table 1. The profiles are drawn for the case where the cell is short circuited. We also show how the light is absorbed in the cell. In all these cases the solution is not bleached and the generating length is unimportant. The current at short circuit is a maximum if the following condition holds:

$$X_e < X_k + X_l \quad (8)$$

The photoelectrochemical collection efficiency,  $N_{hv}$  (ref. 3) describes the flux of electrons from the cell divided by the incident flux of photons. For the conditions given by equation (8) it is equal to its maximum value of unity for a cell with differential electrode kinetics, (cases 2 and 3 of Table 1). All the photons are trapped close to the illuminated electrode and turned into current. For the concentration cell the maximum value of  $N_{hv}$  is  $\frac{1}{2}$  (S. W. Feldberg, personal communication). Even though the photons are trapped close to the illuminated electrode, the fact that the Y,Z couple is not electroactive on the dark electrode means that at short circuit the concentration of B has to be equal at the two electrodes. This in turn means that the photogenerated flux of B partitions equally between diffusion away from the illuminated electrode and diffusion away from the dark electrode after reaction at both electrodes.

Although the condition given in equation (8) maximises the current developed by the cell, the power also depends on the voltage at which the current is produced. The maximum power is found for cells in the hatched region of Fig. 2. For concentration cells it is essential to have the cell length,  $X_l$ , greater than the reaction length,  $X_k$ , or else B can diffuse all over the cell producing a uniform concentration profile and hence very little power. For the cells with differential electrode kinetics, increasing the concentration of Y increases the potential difference developed by the cell through the effect of Y on the potential of the Y,Z half cell at the dark electrode. But increasing the concentration of Y also increases the rate of the back reaction  $B + Y$  and hence decreases

**Fig. 2** Typical concentration profiles across photogalvanic cells. The illuminated electrode is on the left and the broken lines show the penetration of the light; the abscissa compares  $X_l$ , the cell length, with  $X_e$ , the absorbance length. The ordinate compares  $X_l$  with  $X_k$ , the reaction length, which describes the decomposition of the photo-generated intermediate B. The solid lines show the concentration of B for the first three cases in Table 1, when the cell is short circuited. In all three cases B reacts on the illuminated electrode. On the dark electrode B is generated, does not react and is destroyed for cases 1, 2 and 3 respectively. The cells are most efficient in the hatched region.

$X_k$ . Thus the optimum power point for this type of cell depends on the concentration of Y and is found in the hatched area close to the line  $X_k = X_e$ . Detailed investigation of the cases where the dye, A, is bleached shows that they produce less power than cases in the hatched region of Fig. 2. The voltage developed by such cells is larger but the current is very much less because the photons are absorbed too far away from the illuminated electrode for the photogenerated B to reach it before decomposing.

The maximum power  $W_{max}$  produced by the concentration cell<sup>1</sup> can be shown to be

$$W_{max} = 0.28 ART\phi I_0 \quad (9)$$

where  $A$  is the area of each electrode.

This is the maximum possible power that can be obtained after optimising the concentrations of the species, the dimensions of the cell and the load on the cell. The conditions for this maximum are:

$$X_e < X_G < X_k < X_l \quad (10)$$

and

$$X_G^3 = X_k^2 X_e \quad (11)$$

The maximum power produced by a cell with differential electrode kinetics can be shown to be<sup>2</sup>:

$$W_{max} = 0.8AF\phi I_0[|\Delta E| + \frac{RT}{F}\{\ln \frac{\phi I_0 e}{k[Z]} - 1.6\}] \quad (12)$$

$$\approx 0.8AF\phi I_0 \Delta E \quad (13)$$

where  $|\Delta E|$  is the difference in standard electrode potentials for the A,B and Y,Z couples.

**Table 2** Characteristic lengths

Name	Symbol and equation	Description
Cell length	$X_l$	Distance between electrodes
Absorbance length	$X_e = (\epsilon a_0)^{-1}$	Unless solution is bleached, the light is absorbed mainly in this distance
Generating length	$X_G = (D/\phi \epsilon I_0)^{1/2}$	Average distance A diffuses in light of intensity $I_0$ before being converted into B
Reaction length	$X_k = (D/k_Y)^{1/2}$	Average distance B diffuses before being converted to A

The conditions for this maximum are:

$$10 X_e \approx X_G \approx \frac{1}{2} X_k < X_l \quad (14)$$

If these conditions are fulfilled then equation (13) describes the maximum power from cells with differential electrode kinetics whether they be case 2 or 3 of Table 1.

## Discussion

For both types of cell we find the same order for the characteristic lengths in equations (10) and (14). The shortest length must be  $X_e$  to absorb all the photons close to the electrode. The inequality  $X_k > X_e$  ensures that the B, that is formed within the distance  $X_e$ , is not decomposed by reaction with Y before it reaches the electrode. The conditions for  $X_G$  ensure that the solution does not become bleached near the illuminated electrode. The condition for  $X_l$ , the distance between the electrodes, means that the dark electrode does not interfere with the trapping of the photons and the reaction of B on the illuminated electrode.

The maximum power that the concentration cell can deliver is given by equation (9). For the maximum power point the current is close to its short circuit value; the collection efficiency is  $0.3\phi$ , and the current density is  $0.3 \phi I_0$ . But the cell voltage is only about  $(RT/F) \ln$  term in the Nernst equation.

One cannot draw significant currents from a concentration cell and at the same time maintain very different concentrations at the two electrodes.

To calculate power outputs from equations (9) and (13) we must select a reasonable value for  $I_0$ . In AM2 solar radiation (of total irradiance  $749 \text{ W m}^{-2}$ ),  $I_0$  values for photons of wavelengths less than 700, 600 and 500 nm are  $1.57 \times 10^{-3}$ ,  $9.46 \times 10^{-4}$  and  $4.2 \times 10^{-4} \text{ mol photons m}^{-2} \text{ s}^{-1}$  respectively<sup>4</sup>. We shall take a value of  $1.6 \times 10^{-3} \text{ mol photons m}^{-2} \text{ s}^{-1}$  as a reasonable estimate of the flux density of photochemically active photons in AM2 sunlight. As relative values of solar spectral irradiance do not vary very greatly with atmospheric conditions<sup>5</sup>, conversion efficiencies calculated from these figures do not vary by more than a few per cent from efficiencies calculated from other solar spectral distributions; absolute outputs, of course, vary with the incoming total irradiance.

Taking  $I_0 = 1.6 \times 10^{-3} \text{ mol photons m}^{-2} \text{ s}^{-1}$  and  $\phi = 1$  we obtain from equation (9)

$$W_{\max}/A = 1.1 \text{ W m}^{-2} \quad (15)$$

This is the maximum power that can be obtained from a photogalvanic concentration cell driven by solar energy. The power conversion efficiency is no more than 0.15% and we conclude that the concentration cell cannot be an effective device for solar energy conversion.

For a cell with differential electrode kinetics, the maximum power is given by equation (13). Not only is the collection efficiency much closer to unity but also the cell voltage is now given by  $\Delta E$  rather than the miserable  $RT/F$  of the concentration cell. The optimum value for  $\Delta E$  is 1.1 V<sup>6</sup>. With this value and the same value of  $I_0$  as above we obtain

$$W_{\max}/A = 140 \text{ W m}^{-2} \quad (16)$$

This corresponds to a power conversion efficiency of 18%. In principle the optimum case for this type of cell is almost as efficient as a silicon solar cell. Nearly all the photons that can drive the reaction are trapped. While in the ideal case negligible energy would be wasted between the absorption of a photon with threshold energy and the formation of B, in the case we have taken the threshold photon energy is 700 nm or 1.8 eV and the flux of electrons is produced at the lesser potential difference of 1.1 V. Had we taken threshold photon energies of 600 or 500 nm the conversion efficiencies would have been 11% and 5% respectively. To achieve this amount of power we have to satisfy equation (14),

however. For typical values of  $D = 10^{-5} \text{ cm}^2 \text{ s}^{-1}$  and  $\epsilon = 10^8 \text{ cm}^2 \text{ mol}^{-1}$  we find

$$X_G \sim 10^{-3} \text{ cm} \quad (17)$$

This means that

$$X_e \sim 10^{-4} \text{ cm} \quad (18)$$

or

$$[A] \sim 10^{-1} \text{ M} \quad (19)$$

Hence the dye, A, has to be rather soluble. Furthermore, the electrochemical rate constant  $k'$ , for the destruction of B on the illuminated electrode must satisfy the condition

$$k' > D/X_e \sim 10^{-1} \text{ cm s}^{-1} \quad (20)$$

If this condition is not satisfied the electrode will not remove all the B that reaches it and some B will be lost by reaction with Y in the bulk of the solution. This is a severe condition as most electrochemical rate constants are less than  $10^{-2} \text{ cm s}^{-1}$ . The condition in equation (14) with the value for  $X_G$  in equation (17) means that the kinetics of the reaction of B with Y must satisfy the condition,

$$k[Y] \sim 40 \text{ s}^{-1} \quad (21)$$

But the concentration of Y must be at least twice the concentration of B generated in the light. This is to ensure that there is no concentration polarisation at the dark electrode. Hence for the optimum case,

$$[Y] > 2[B] \sim 10^{-2}[A] \sim 10^{-3} \text{ M} \quad (22)$$

Substitution in equation (21) gives  $k < 4 \times 10^3 \text{ M}^{-1} \text{ s}^{-1}$ . Thus from equations (19) to (21) we may summarise the contradictory requirements for the optimum case: (1) the species, A, must be rather soluble,  $[A] > 0.1 \text{ M}$ ; (2) the electron transfer reaction of the A,B couple on the illuminated electrode must be very rapid,  $k' > 10^{-1} \text{ cm s}^{-1}$ ; (3) considering the thermodynamic driving force corresponding to  $\Delta E$  of 1.1 V, the electron transfer reaction of B + Y must be sluggish:  $k < 4 \times 10^3 \text{ M}^{-1} \text{ s}^{-1}$ ; (4) the electron transfer reaction that forms B and Y from  $A^* + Z$  must be rapid. Electron transfer reactions that obey the Marcus theory<sup>7</sup> are unlikely to satisfy all the conditions 2, 3 and 4 (S. W. Feldberg, personal communication).

The detailed treatment presented elsewhere<sup>2</sup> allows the optimum conditions and the power that can be produced for any particular system to be calculated. For instance, if we relax the condition of equation (14), so that  $X_e = X_G = X_k$  then we find that  $[A] \sim 10^{-2} \text{ M}$ ;  $k' > 10^{-2} \text{ cm s}^{-1}$ ;  $k < 4 \times 10^4 \text{ M}^{-1} \text{ s}^{-1}$ .

It may be possible to find a system that satisfies these conditions. For this case the power is only reduced by a factor of 2 from the optimum to about 9% and

$$W_{\max}/A = 70 \text{ W m}^{-2} \quad (23)$$

It is clear that the processes occurring in a photogalvanic cell are controlled by the photochemistry, homogeneous kinetics, mass transfer and electrochemical kinetics of the system. The power developed depends on the concentrations of all the species, the intensity of illumination, diffusion lengths at the electrode, the electrode kinetics, the spacing of the electrodes and the load on the cell. The optimum performance of the cell can only be obtained by carefully selecting the best values for all these variables.

We thank Dr Stephen Feldberg for helpful discussions, and Mr Stephen Fisher and Mr Andrew Foulds for their criticisms.

# Cordilleran Benioff zones

Peter J. Coney & Stephen J. Reynolds

Department of Geosciences, University of Arizona, Tucson, Arizona 85721

*Ages of late Mesozoic–early Cainozoic igneous rocks in south-western North America indicate a magmatic arc initiated near the continental margin, swept over 1,000 km northeastward, then swept back, all in 110 Myr. The sweep in and return are interpreted as due to flattening of a Benioff zone to  $<15^\circ$  followed by rapid collapse.*

THE geometric relationship between trench, dipping Benioff zone, and magmatic arc is well established in plate tectonics<sup>1–4</sup>. In active arc–trench systems, distance from the trench axis to the main volcanic front or magmatic arc axis varies from as little as 75 km to over 400 km<sup>5,6</sup>. Much of this variation is due to the width of the accretionary prism which seems to control the initial angle of descent of subducting slabs<sup>4,5</sup>. Once the slab is below a depth of 25–75 km the angle of descent usually steepens, but the descent angle of deeper segments of Benioff zones can range from  $90^\circ$  to as little as  $15^\circ$  (ref. 7). Surface manifestation of arc activity can extend over some width and stands between 100 km and 300 km above the Benioff zone<sup>6</sup>. Based on this geometry, the distance the magmatic arc activity can lie inboard from the trench is controlled by the dip-angle of the descending slab.

Extrapolation of this model back through Mesozoic time in the North American Cordillera<sup>8–10</sup> has not been universally accepted. Here, igneous activity of arc type reached inboard in excess of 1,000 km from assumed marginal trenches and many have doubted the existence of resulting low-dipping Benioff

zone geometry<sup>11–13</sup>. We propose that widespread magmatic activity of arc type in southwestern North America during late Mesozoic to middle Tertiary time is consistent with Benioff zone geometry, and we show evidence that inferred changes in angle of Benioff zone dip can be tracked in time.

## Magmatic arc activity

Figure 1 shows the distribution of all available radiometric ages on igneous rocks from southern California, Arizona, New Mexico and west Texas in southwestern United States with a few additional ages from northern Baja California and Sonora in Mexico. The ages range from 160 Myr to about 15 Myr. The dated rocks have chemical compositions normally considered of magmatic arc type and include both volcanic and plutonic occurrences. The age dates are mostly by the K/Ar method supplemented with a few by Rb/Sr and U/Pb methods. Each dated occurrence has been examined for geological setting and method used. All available ages were used on Fig. 1 with the following exception: in the case of plutonic rocks from the Peninsular batholith in the western part of the region, multiple intrusion has caused extensive resetting of K/Ar ages<sup>14</sup>. As a result, only concordant biotite–hornblende pairs were used. In the absence of U/Pb ages concordant hornblende–biotite K/Ar pairs have been shown to be more reliable in belts of concentrated prolonged batholith emplacement<sup>15</sup>. Further east where plutonism was more dispersed single mineral dates were used. Throughout the region dates on volcanic rocks were considered accurate, providing they were geologically consistent and the method used indicated reliability.

**Fig. 1** Distribution of radiometric age determinations in southwestern United States and adjacent northwestern Mexico. Published dates from refs 14, 18–20, 44, 45. S. B. Keith and S. J. Reynolds compiled dates, lists and maps which are available from P. Damon, University of Arizona. Unpublished ages taken from refs 23, 44, and P. Damon, R. Nielson and W. Rehrig personal communication. T, Tucson; S, Santa Rita; SAF, San Andreas Fault; CA, California; AZ, Arizona; NM, New Mexico; BC, Baja California; GC, Gulf of California; SN, Sonora; CH, Chihuahua; TX, Texas.

**Fig. 2** *a*, Distribution of radiometric ages from Fig. 1 plotted as a function of time. Dates projected into a line passing through Tucson, Arizona, and Santa Rita, New Mexico after closure of Gulf of California.  $\circ$ , single mineral K/Ar ages on plutons in southeastern California. *b*, Hypothetical arc-trench system scaled to southwestern North America. Various dip-angles of Benioff zones shown with points of intersection with 150 km depth line. *c*, Graphical representation of function controlling distance from trench to magmatic arc with varying Benioff zone dip angles.

Figure 2a shows the distribution of radiometric ages plotted as a function of time. To construct this figure, the Gulf of California was first closed, bringing dates south-west of the San Andreas Fault about 300 km southeastward relative to dates north-east of the fault. This reconstruction restores the age distribution to a pattern more like the original distribution before post-14 Myr opening of the Gulf of California and displacement on the San Andreas Fault. A line was then drawn from the western edge of the continent through Tucson, Arizona and Santa Rita, New Mexico, approximately perpendicular to the restored continental margin and the assumed late Mesozoic-mid-Tertiary trench. All the ages on Fig. 1 were then projected on to this line to produce Fig. 2a.

The scattering of ages at the top of Fig. 2a is the youngest part of a group of ages which represent a north-west-south-east trending magmatic arc across southern Arizona during Jurassic time<sup>16</sup>. This arc was extinguished in latest Jurassic time. Arc activity then seems to have jumped south-west towards the supposed site of the trench in early Cretaceous time. This jump established an arc near the continental margin and produced the Peninsular batholith of southern California-northern Baja California<sup>14,17</sup>.

Ages on the Peninsular batholith form a cluster at the far western edge of Fig. 2a ranging from 125 Myr to about 85 Myr. The dates shown are mostly K/Ar concordant biotite-hornblende pairs<sup>18-20</sup>, and they define an array which is oldest in the west and younger to the east across the batholith. Silver *et al.*<sup>17</sup> report a similar, but slightly older, trend in U/Pb ages. It can be seen from Fig. 2a that the magmatic pulse, apparently of just over 20 Myr duration, continues its sweep eastward, progressively decreasing in age. It eventually crosses the entire southwestern Cordillera, reaching central New Mexico 1,000

km inboard from the assumed trench about 40 to 55 Myr ago. Anderson and Silver<sup>21</sup> report a similar, but presumably slightly older, trend in U/Pb ages from Baja California across Sonora.

At its most easterly limit near 40 to 55 Myr, the magmatic pulse is scattered and somewhat diffuse. It then starts a rapid return migration, sweeping back across the same terrain over which it had earlier advanced, reaching southern California 15 to 20 Myr ago. Thus, in a period of just over 100 Myr, arc magmatism swept continuously inboard 1,000 km, then swept back to where it had originated. The dashed lines on Fig. 2a are a gross envelope superimposed on the data bracketing the magmatic arc distribution. Since most of the plutonic ages plotted are by the K/Ar method, they are believed to represent times when the igneous rocks passed through cooling temperatures somewhat less than 'emplacement' temperatures. We note, however, that the few published U/Pb ages fall within the envelope, and we assume that the average emplacement age for the magmatic arc at any given time probably falls somewhere within the envelope as well. At about 15 Myr, the character of igneous activity of the entire region analysed abruptly changed. The chemistry became distinctly bi-modal, with much basalt, and was associated with Basin and Range rifting<sup>22,23</sup>, initiation of movement on the San Andreas Fault, and eventual opening of the Gulf of California.

### Analysis and interpretation

Figure 2b shows a hypothetical arc-trench system scaled to a geometry likely to have existed in southwestern North America during mid-Cretaceous to mid-Tertiary time, with various Benioff zone dip-angles ranging from 80° to 10°. Also shown are distances inboard from the trench where the Benioff zone intersects the 150 km depth line. This depth is presumed to lie

below the locus of magmatic arc activity at the surface<sup>6</sup>. The function controlling the position of the magmatic arc axis with varying Benioff zone dip is: distance = depth  $\times \cot \theta$ , where  $\theta$  is the dip. In other words, with decreasing dip the distance from the trench to the arc increases ever more rapidly Fig. 2c.

We suggest that the pattern of ages on Fig. 2a reflects the progressive flattening of a Benioff zone beneath southwestern North America from about 130–110 Myr to about 55–40 Myr, followed by a rapid steepening of dip from 40 Myr to about 15 Myr. This decreasing then increasing Benioff zone dip first swept a magmatic arc 1,000 km inboard from the trench until 55–40 Myr, then swept it back towards the continental margin by about 20 Myr.

Figure 3 is derived from Fig. 2a and shows the change in Benioff zone dip as a function of time beneath southwestern North America based on a best-fit curve through the centre of the envelope enclosing the age dates. Figure 4, also derived from Fig. 2a, is the value of the first derivative of the age distribution function and shows the velocity of the magmatic arc locus with respect to the trench as it swept inboard then back between 130 and 15 Myr. This velocity apparently attained almost 3 cm yr<sup>-1</sup> on the sweep in, collapsed to zero at the bend near 45 Myr, then increased to over 4 cm yr<sup>-1</sup> on the return. The duration of arc activity at any given place averages over 20 Myr during the sweep eastward and is somewhat less on the sweep back. The width of arc activity at any given time is initially narrow at steep angles of dip (about 100 km), but very wide (over 600 km) at low angles of dip or during periods of rapid migration.

## Discussion

If our interpretation that shifting magmatic arc patterns in southwestern North America are due to changes in dip of Cordilleran Benioff zones is correct, some explanation must be sought for the changing dips. Luyendyk<sup>24</sup> suggested that rates of convergence at subduction zones influenced Benioff zone dip with his formula: dip = arc sin  $V_z/V_0$ , where  $V_z$  is the natural rate a slab sinks due to gravity, and  $V_0$  is the rate of convergence. Thus, the higher the rate of convergence the lower the angle of dip. It has also been suggested that an actively driving continental plate, with a subduction zone dipping beneath the leading edge, pushes the subduction zone ahead, over-riding and entraining the Benioff zone below and decreasing the dip<sup>25</sup>. Other factors, such as age (temperature) and emboliment of aseismic ridges, might reduce slab density and influence Benioff zone dip<sup>26</sup>. Rates of convergence between an actively driving North America plate and Farallon plate may have increased during late Cretaceous–early Tertiary time, flattening the Benioff zone beneath western North America. Some time between 40–55 Myr the rate slowed, causing increase in Benioff zone dip and the resulting return sweep between 40 and 20 Myr.

Plate reconstructions based on assumed movement of Pacific and African plates over hotspots in the mantle since 135 Myr, although still suspect, yield vector subtraction derived convergent rates between North America and Farallon plates<sup>27,28</sup>. From 80 Myr to about 45 Myr the computed rates of convergence reach values in excess of 12 cm yr<sup>-1</sup>. The age of the bend in the Hawaii–Emperor seamount chain is placed at about 45 Myr (refs 29, 30) and is assumed to mark a change in direction of Pacific plate motion from northward to more north westward. After the change in direction, convergent rates between the two plates fall to less than 8 cm yr<sup>-1</sup>. We note that the age of the Hawaii–Emperor bend is the same as the age of the bend in Fig. 2a, and that high derived convergent rates correlate with the sweep inboard during Laramide time while the lower rates of post-45 Myr time correlate with the sweep back during mid-Tertiary time. Using Luyendyk's formula and a rate of convergence of 12 to 14 cm yr<sup>-1</sup>, the Benioff zone dip attains 20°. Slower rates of convergence between 6 and 8 cm yr<sup>-1</sup> yield dips from 40° to 60°. The high

Fig. 3 Benioff zone dip angle as a function of time beneath southwestern North America. Graph derived from best-fit curve through data of Fig. 2a. A 15% post-15 Myr extension due to Basin and Range faulting has been removed from Fig. 2 to construct Fig. 3.

rates of convergence, coupled with a low-dipping Benioff zone during Laramide orogeny are thought to explain extensive deep-seated compressive thrusting which extended as far inboard from the trench as did the arc magmatism<sup>27,31</sup>.

The sweep in from 130 Myr to about 45 Myr includes two classic orogenic episodes in Cordilleran tectonics: the Sevier orogeny during mid-Cretaceous to about 80 Myr and the Laramide orogeny from 80 Myr to about 45 Myr (refs 9, 32, 33). The return sweep between 40 Myr and about 15 Myr includes what has been termed the mid-Tertiary orogeny<sup>34,35</sup>, or the ignimbrite flare-up<sup>28</sup>. In terms of magmatic arc activity, these 'orogenies' are here seen as a continuum broken only by the turn-around near 45 Myr which ended Laramide events and initiated the mid-Tertiary ignimbrite flare-up in southern Arizona. We note the latter part of the sweep inboard (Laramide time) produced a major percentage of North American copper porphyry deposits in southern Arizona, New Mexico, and Sonora. The return sweep across the same region produced essentially none.

We have preliminary evidence that the shifting magmatic arc patterns described for the southwestern Cordillera are related to similar patterns further north. Arc activity in the Sierra Nevada and Idaho batholiths began to disappear soon after 80 Myr (refs 19, 35). Just afterward a very sparse magmatic pulse swept eastward and rapidly died, producing the well

Fig. 4 Velocity of magmatic arc axis as a function of time. Graph derived from best-fit curve through data of Fig. 2a. A 15% post-15 Myr extension due to Basin and Range faulting has been removed from Fig. 2 to construct Fig. 4.

known Laramide 'igneous gap' between about 70 Myr and 55 Myr throughout the north-west and west-central United States<sup>36,10</sup>. At about 55 Myr the north-west erupted violently with wide-spread Challis-Absaroka volcanism and shallow plutonism<sup>36</sup>. This pattern then swept out of Washington, Idaho, Montana, and Wyoming, and moved progressively southwestward across western Utah and Nevada as the ignimbrite flare-up of the Great Basin between 40 and 20 Myr (refs 37-39). We interpret the sweep in and rapid extinguishing of arc activity as the result of the same flattening of a Benioff zone we describe to the south, the only difference being that in the north the dip became so shallow arc activity was impossible. The igneous gap extending from southern Ecuador to southern Peru, accompanied by an essentially horizontal Benioff zone<sup>40</sup>, is the present-day analogue. The Challis-Absaroka flare-up and subsequent return sweep of arc activity southwestward across the Great Basin would be the same return sweep we describe to the south and due to the same cause—a rapid increase in dip. Seen this way, the mid-Tertiary outburst of ignimbrites in the central and southern Cordillera becomes more comprehensible. Lipman *et al.*<sup>10</sup> called the outburst a magmatic arc related to subduction. We agree with this interpretation, and add that with the better resolution of time-space plots based on extensive radiometric dating the volcanism can be further seen as the rapid retrograde sweep of a magmatic arc toward the trench resulting from gravitational collapse and steepening of a Tertiary Benioff zone. Calling on complex back-arc diapirs<sup>41</sup> to explain mid-Tertiary volcanism in the Great Basin now seems unnecessary.

The data presented here suggest arc activity in southwestern North America was essentially continuous between 130 Myr and about 15 Myr. If a Kula-Farallon triple junction migrated up the North America plate margin during late Cretaceous-early Tertiary time, as suggested from some reconstructions<sup>42</sup>, we do not see evidence of its passage. The data seem more consistent with, but do not prove, continuous subduction of the Farallon plate during this time. Progressive destruction of the Pacific-Farallon spreading centre and Mendocino fracture zone along the North America plate margin during late Tertiary time<sup>42</sup> has bearing on interpretation of the youngest ages in the data array. Most reconstructions place this event between 30 Myr and 20 Myr, with initial contact somewhere along the coast of northernmost Baja California<sup>43</sup>. It is not certain to what degree the last part (25 Myr to 15 Myr) of the post-40 Myr collapse and rapid steepening of the Benioff zone was due to cessation of subduction caused by the change in plate geometry. Regardless, an arc activity delay-time of 5-10 Myr after slab truncation is predictable<sup>44</sup>.

The rapid retrograde migration of arc activity toward the trench after 40 Myr does not require excessive sinking rates

of the subducting slab. For example, between 40 Myr and 20 Myr the increase in dip-angle was about 20° (Fig. 3). This implies an approximate average vertical descent rate of about 1 cm yr<sup>-1</sup>. From 20 Myr to 15 Myr the increase in dip-angle was about 40° which yields an average sinking rate of about 5 cm yr<sup>-1</sup>. This 5 cm yr<sup>-1</sup> is the velocity Luyendyk<sup>84</sup> gives the natural vertical sinking rate ( $V_z$ ) of a slab due to gravity. This suggests the slab may actually have been detached and freely sinking after  $\pm$  25 Myr due to destruction of the East Pacific spreading centre and initiation of the San Andreas transform<sup>42</sup>.

# Regulation of protein synthesis, intracellular electrolytes and cataract formation *in vitro*

Toshimichi Shinohara & Joram Piatigorsky

Section on Cellular Differentiation, Laboratory of Molecular Genetics, National Institute of Child Health and Human Development, National Institutes of Health, Bethesda, Maryland 20014

*Control of protein synthesis is associated with changes in the ratio of intracellular Na<sup>+</sup> to K<sup>+</sup> in the cultured embryonic chick lens. Correlations of intracellular Na<sup>+</sup>/K<sup>+</sup> ratios with crystallin synthesis and cataract formation in vitro suggest that the Na<sup>+</sup>/K<sup>+</sup> ratio may have an important role in the regulation of protein synthesis during cataractogenesis.*

CATARACTS, or lens opacities, represent a primary cause of seriously impaired vision and even blindness. At present, a cataract that has progressed beyond the initial stages cannot be reversed, forcing the patient to have the affected lens removed in order to restore clear vision. Cataracts are initiated by or associated with a variety of factors, including physical trauma, ageing, metabolic stress, hereditary defects, disease, ionising radiation and microwaves<sup>1</sup>. Although the

mechanism of cataractogenesis has not been definitively established for any one type of lens opacity, considerable evidence indicates that osmotic imbalance<sup>2</sup> and protein aggregation<sup>3-5</sup> may play prominent parts.

We have reported<sup>6</sup> that cortical cataracts are formed within 3 h after explantation of the embryonic chick lens into a defined culture medium (Ham's F-10<sup>7</sup>) (see Fig. 1). This experimental cataract seems to be caused by the trauma of detaching the vitreous body, a gelatinous connective tissue matrix. The initiation of this experimental cataract is associated with a specific alteration in the synthesis of  $\delta$ -crystallin, the principal protein of the embryonic chick lens<sup>8</sup>.  $\delta$ -Crystallin represents 60–80 % of the protein present in these lenses<sup>9-13</sup> and can be resolved into two bands with molecular weight near 50,000 and 48,000 by electrophoresis in a sodium dodecylsulphate-urea-polyacrylamide gel<sup>14</sup>. Clear lenses synthesise the proteins in these two bands in a ratio of approximately 1 : 3 in favour of the lower molecular weight band. In vitreous-free lenses developing cortical opacities the ratio of synthesis of proteins in these two bands is reversed to approximately 3 : 1 in favour of the higher molecular weight band. This alteration in protein synthesis is associated only with the initiation of the cataract, since these  $\delta$ -crystallin polypeptides are synthesised in the normal ratio after the lens has remained in culture for 24 h, despite persistence of the cortical opacity<sup>6</sup>.

Here we explore the possibility that the alteration of  $\delta$ -crystallin synthesis in the cultured lens is due to an increase in the intracellular concentration of  $\text{Na}^+$  and a decrease in the intracellular concentration of  $\text{K}^+$ , since several reports have shown that cataracts are associated with  $\text{Na}^+$  influx and  $\text{K}^+$  efflux<sup>2,15-20</sup>. In addition, one investigation has shown that stripping the vitreous body from a cultured rabbit lens accelerates cataract formation<sup>21</sup> and causes an increase in  $\text{Na}^+$  and a decrease in  $\text{K}^+$  concentration within the lens<sup>22</sup>. Moreover, experiments with bacterial<sup>23</sup> and mammalian<sup>24</sup> cells have indicated the importance of  $\text{K}^+$  for the intracellular control of protein synthesis, and investigations of cell-free translation<sup>25</sup> have provided evidence that  $\text{Na}^+$  and  $\text{K}^+$  ions can discriminate between different mRNAs to allow preferential translation at different ionic strengths. Our data indicate the changes in the intracellular concentrations of  $\text{Na}^+$  and  $\text{K}^+$  cause the alteration of  $\delta$ -crystallin synthesis in the embryonic chick lens cultured without its vitreous body. This raises the possibility that the intracellular levels of these ions also contribute to the control of differential protein synthesis in other eukaryotic cells; this in turn may influence cellular growth, differentiation and pathogenesis.

### $\text{Na}^+$ and $\text{K}^+$ in cultured lenses with and without vitreous body

$\text{Na}^+$  and  $\text{K}^+$  concentrations were determined in the embryonic chick lens immediately after explantation, after 3 h of culture with its vitreous body attached, and after 3 or 24 h of culture with its vitreous body detached (Table 1). At the time of explantation, the concentrations of these ions were similar to those found for lenses of other species<sup>26</sup>, with  $\text{Na}^+$  being considerably lower than  $\text{K}^+$ . The  $\text{Na}^+$  and  $\text{K}^+$  concentrations remained the same after the lenses were cultured for 3 h with their vitreous bodies; these lenses with attached vitreous body have been shown to be transparent and synthesise the proteins comprising the two bands of  $\delta$ -crystallin in the normal ratio of 1 : 3 in favour of the lower molecular weight band<sup>6</sup>. By contrast, after removal of the vitreous body, the  $\text{Na}^+$  concentration increased approximately sixfold and the  $\text{K}^+$  concentration decreased approximately 2.5-fold within 3 h; these vitreous-free lenses have been shown to possess cortical cataracts and synthesise the proteins of the two  $\delta$ -crystallin bands in a ratio of approximately 3 : 1 in favour of the higher molecular weight band<sup>6</sup>.

**Fig. 1** Diagrammatic representation of a cross section of a 15-d-old embryonic chick lens. The nuclei in the centre of the fibre mass (nuclear fibre cells) are starting to become pycnotic and will eventually disintegrate. The stippled zone represents the area which becomes opaque when the lens is cultured after its vitreous body has been removed from the posterior surface. The vitreous body (not shown) occupies a major part of the eye and consists of an avascular, viscous connective tissue matrix containing fibroblasts, collagenous material and other proteins, mucopolysaccharides and organic substances.

After 24 h *in vitro* without the vitreous body, the  $\text{Na}^+$  concentration had returned to nearly its initial value at explantation; the vitreous-free lens after 24 h *in vitro* has been shown to still have the cortical cataract, but to return to a relatively normal pattern of  $\delta$ -crystallin synthesis<sup>6</sup>. Since the intracellular  $\text{K}^+/\text{Na}^+$  ratio and pattern of  $\delta$ -crystallin synthesis are markedly different in the lenses cultured with or without the vitreous body, we were encouraged to pursue the relationship between the intracellular concentrations of  $\text{Na}^+$  and  $\text{K}^+$  and the ratio of synthesis of the  $\delta$ -crystallin polypeptides.

### Effect of ouabain on protein synthesis in cultured lenses

In order to alter the intracellular concentrations of  $\text{Na}^+$  and  $\text{K}^+$  without removing the vitreous body, explanted lens-vitreous preparations were treated with ouabain, an inhibitor of  $\text{Na}^+/\text{K}^+$  ATPase activity<sup>27</sup>. This enzyme is responsible for the permeability of  $\text{Na}^+$  and  $\text{K}^+$  in eukaryotic cells. Inhibition of its activity with ouabain is known

**Table 1**  $\text{K}^+$  and  $\text{Na}^+$  concentrations in embryonic chick lenses

	mEq per kg $\text{H}_2\text{O}$		
	$\text{K}^+$	$\text{Na}^+$	$\text{K}^+/\text{Na}^+$
Immediately after explantation	112 $\pm$ 11	17 $\pm$ 3	6.6
Cultured 3 h, + vitreous body	110 $\pm$ 7	16 $\pm$ 6	6.9
Cultured 3 h, - vitreous body	40 $\pm$ 3	84 $\pm$ 9	0.5
Cultured 24 h, - vitreous body	47 $\pm$ 8	29 $\pm$ 18	1.6

Four to eight lenses from 15-d-old chick embryos with or without their vitreous body were cultured in plastic tissue culture dishes (Falcon, 60  $\times$  15 mm) containing 10 ml of Ham's F-10 medium supplemented with fructose (848 mg per 100 ml); all assays were performed on lenses stripped of their vitreous body. Each determination represents an average of five to eight experiments. The lenses were washed quickly in groups of four with deionised water, placed in pyrex test tubes (previously soaked overnight in concentrated nitric acid to remove adhering  $\text{Na}^+$ ), dried at 75  $^\circ\text{C}$  for 24 h, dissolved in 100  $\mu\text{l}$  of concentrated nitric acid for several hours at room temperature and diluted with 40 ml of deionised water.  $\text{K}^+$  was determined by flame photometry and  $\text{Na}^+$  by atomic absorption spectrometry (Perkin-Elmer model 603). The average water content of the embryonic lenses was 85 % of their total weight. Corrections were made for ions in the extracellular space of the lens, which was determined by experiments with  $^3\text{H}$ -inulin.

**Fig. 2** Effect of ouabain on the concentrations of Na<sup>+</sup> and K<sup>+</sup> in cultured embryonic chick lenses. Each point on the graph represents an average of three experiments; the vertical lines indicate the range of values obtained in the three tests. The lenses were cultured with their vitreous body and analysed for Na<sup>+</sup> and K<sup>+</sup> as given in Table 1.

to increase the Na<sup>+</sup> and decrease the K<sup>+</sup> concentration in cultured lenses of other species<sup>28-31</sup>. Ouabain caused a reciprocal change in the relative concentrations of the ions of the order of tenfold for each ion in the cultured lenses (Fig. 2). The ouabain-treated embryonic lens-vitreous preparations developed a diffuse opacity covering the entire epithelium and the most anterior aspect of the fibre mass. The bulk of the fibres remained clear, however, even after 24 h *in vitro*, and did not develop cortical cataracts unless the vitreous body was detached.

Incorporation of <sup>35</sup>S-methionine into protein was severely affected by ouabain treatment. Lenses labelled for 3 h with <sup>35</sup>S-methionine incorporated about 90% less isotope into their total protein after 24 h of preincubation with  $1 \times 10^{-4}$  M ouabain than after a comparable preincubation in the absence of the drug. The pattern of incorporation into  $\delta$ -crystallin was strikingly altered in lenses treated with ouabain. Incorporation of <sup>35</sup>S-methionine into the protein of the lower molecular weight  $\delta$ -crystallin band was inhibited by at least 95% after 8 h of culture with ouabain, while incorporation of the <sup>35</sup>S-methionine into the protein of the higher molecular band was only inhibited 50–60% (Fig. 3). This greater inhibition of methionine incorporation into the protein of the lower molecular weight band of  $\delta$ -crystallin persisted as long as ouabain was present in the culture medium. The staining patterns of the polyacrylamide gels, reflecting the absolute amount of protein present in each band, were similar in the preparations from lenses cultured with or without ouabain. The difference in <sup>35</sup>S-methionine incorporation into the proteins of the two  $\delta$ -crystallin bands was apparently not due to differential degradation of the newly synthesised polypeptides, since the protein in neither band was degraded in lenses labelled with <sup>35</sup>S-methionine

for 3 h in the absence of ouabain and subsequently incubated for 24 h in the presence of ouabain and the absence of protein synthesis (inhibited by  $10 \mu\text{g ml}^{-1}$  cycloheximide). Since the rate of the total uptake of <sup>35</sup>S-methionine into the lens did not decrease over the 24 h of culture (data not shown), the differential decrease of <sup>35</sup>S-methionine incorporation into protein seems to be due to differential inhibition of synthesis of the  $\delta$ -crystallin polypeptides.

It is important to note that the change in the ratio of synthesis of the  $\delta$ -crystallin polypeptides occurred in the epithelium and the fibre mass of the ouabain-treated lens, but was confined to the fibre mass in the vitreous-free lens. We believe that this difference in the localisation of the alteration of  $\delta$ -crystallin synthesis is due to a corresponding difference in the localisation of the changes in the levels of Na<sup>+</sup> and K<sup>+</sup>. The Na<sup>+</sup>,K<sup>+</sup> ATPase activity of the lens is located principally<sup>29,32,33</sup>, although apparently not exclusively<sup>34,35</sup>, in the epithelium. The ionic balance of the lens is thus thought to be governed by a pump-leak system<sup>36</sup>. Na<sup>+</sup> diffuses into the lens through the fibre mass at the posterior surface and is transported out of the lens through the epithelium at the anterior surface; by contrast, K<sup>+</sup> is transported into the lens through the epithelium and diffuses out of the lens through the fibre mass. Thus, detaching the vitreous body from the posterior surface may increase Na<sup>+</sup>

**Fig. 3** Effect of  $1 \times 10^{-4}$  M ouabain on the relative incorporation of <sup>35</sup>S-methionine into the proteins of the higher and lower molecular weight bands of  $\delta$ -crystallin. The lenses were cultured with their vitreous body as for Table 1. Each point on the graph represents an average of three experiments; the vertical lines indicate the range of values obtained in the three tests. Lenses were labelled individually for 3 h in 1 ml of medium containing 250  $\mu\text{Ci}$  of <sup>35</sup>S-methionine (New England Nuclear, 450 Ci mmol<sup>-1</sup>). One to 2  $\mu\text{g}$  of total homogenate protein was examined by electrophoresis in a discontinuous, 10% polyacrylamide gel containing 0.1% sodium dodecylsulphate and 8 M urea as described elsewhere<sup>14</sup>. The stained  $\delta$ -crystallin bands were cut from the gel, dissolved in 100  $\mu\text{l}$  of hydrogen peroxide and assayed for radioactivity by scintillation counting. The % inhibition of incorporation by ouabain into the protein of each band was calculated by dividing the amount of radioactivity in that band at each time point by the amount of radioactivity in the same band from lenses labelled for 3 h without ouabain immediately after explantation. ●, Higher molecular weight band; ○, lower molecular weight band.

diffusion into the lens without significantly changing the concentrations of  $\text{Na}^+$  and  $\text{K}^+$  in the epithelium. Ouabain treatment, however, should increase the  $\text{Na}^+$  concentration and decrease the  $\text{K}^+$  concentration in both the fibre mass and the epithelium by inhibiting the  $\text{Na}^+, \text{K}^+$  ATPase activity of the lens.

In addition to the alteration of  $\delta$ -crystallin synthesis, ouabain treatment also caused the differential inhibition of synthesis of other proteins in the cultured lenses. This was best observed when examining the isolated epithelium where  $\delta$ -crystallin represents a much smaller proportion of the total protein than in the fibre mass. The autoradiograms shown in Fig. 4 demonstrate the marked inhibition of synthesis of a  $\beta$ -crystallin component as well as that of the protein in the lower molecular weight  $\delta$ -crystallin band in lenses treated with ouabain. The synthesis of this  $\beta$ -crystallin polypeptide is also inhibited in lenses developing cortical cataracts in culture after their vitreous body has been removed. Inspection of the autoradiograms of Fig. 4 reveals a number of other differences in the relative amount of  $^{35}\text{S}$ -methionine incorporated into different bands of protein. Since equal amounts of radioactivity were applied to the gels, the synthesis of some bands of protein seems to be selectively stimulated by ouabain, but these actually represent proteins whose synthesis is not appreciably inhibited by the agent.

### Regulation of protein synthesis by $\text{Na}^+$ and $\text{K}^+$

To test the effect of  $\text{Na}^+$  and  $\text{K}^+$  on protein synthesis we examined cultured lenses with different intracellular concentrations of these ions. This was made possible by varying the amounts of  $\text{Na}^+$  and  $\text{K}^+$  in the culture medium of the lenses, which were permeable to these cations after treatment with ouabain. Determination of the intralenticular  $\text{Na}^+$  and  $\text{K}^+$  concentrations confirmed that the ouabain-treated lens was permeable to  $\text{Na}^+$  and  $\text{K}^+$ , and that these ions were at a similar concentration within the lens and in the medium. Tests with  $^3\text{H}$ -inulin, a compound which does not penetrate into cells, established that the ions were principally in the lens cells rather than in the extracellular space.

The incorporation of  $^{35}\text{S}$ -methionine into protein was sensitive to changes in the total intracellular concentration of  $\text{Na}^+$  and  $\text{K}^+$ .  $^{35}\text{S}$ -methionine incorporation was severely inhibited at combined  $\text{Na}^+$  and  $\text{K}^+$  concentrations above 200 mM or below 10 mM.  $\text{K}^+$  concentrations above 96 mM almost completely inhibited  $^{35}\text{S}$ -methionine incorporation into protein. These inhibitions of  $^{35}\text{S}$ -methionine incorporation into protein at different ionic strengths were apparently due to decreases in protein synthesis rather than  $^{35}\text{S}$ -methionine uptake since the total accumulation of radioactivity was not appreciably different in lenses cultured in the presence of ouabain in medium containing different concentrations of  $\text{Na}^+$  and  $\text{K}^+$ .

The most striking result of these tests was the sensitivity of the ratio of synthesis of the  $\delta$ -crystallin polypeptides to the variations in the concentrations of  $\text{Na}^+$  and  $\text{K}^+$ . The differential inhibition of synthesis of the protein in the lower molecular weight band of  $\delta$ -crystallin induced by ouabain (Fig. 5b) was partially overcome by increasing the concentration of  $\text{K}^+$  (Fig. 5c, d). Lowering the  $\text{Na}^+$  concentration also increased the relative amount of  $^{35}\text{S}$ -methionine incorporated into the protein in the lower molecular weight band of  $\delta$ -crystallin (Fig. 5e, f). The differential synthesis of the  $\delta$ -crystallin polypeptides does not seem to be simply a function of the total intracellular concentration of  $\text{Na}^+$  plus  $\text{K}^+$  because the protein in the lower molecular weight band was not synthesised at 154 mEq per kg of water of  $\text{Na}^+$  plus  $\text{K}^+$  (Fig. 5b) but was synthesised at higher (Fig. 5c-e) and lower (Fig. 5f, g) concentrations of intracellular  $\text{Na}^+$  plus  $\text{K}^+$ . Furthermore, the combined concentration of  $\text{Na}^+$  plus  $\text{K}^+$  in lenses cultured

**Fig. 4** Autoradiograms demonstrating the effect of ouabain on protein synthesis in the epithelium of the embryonic chick lens. Lenses were cultured in the absence (a) or presence (b) of  $1 \times 10^{-4}$  M ouabain for 24 h and then labelled with  $^{35}\text{S}$ -methionine for 3 h as given in Fig. 3. The epithelium was separated from the fibre mass and the proteins subjected to discontinuous polyacrylamide gel electrophoresis in the presence of sodium dodecylsulphate and urea<sup>14</sup>. The gels were stained and autoradiographed. The arrows on the right denote the almost complete inhibition of  $^{35}\text{S}$ -methionine incorporation into the proteins in the lower molecular weight  $\delta$ -crystallin band and into one  $\beta$ -crystallin band by ouabain. The staining patterns of the two samples were the same and were similar to the autoradiographic pattern of (a).

for 3 h with or without the vitreous body was the same, but the ratio of synthesis of the  $\delta$ -crystallin polypeptides has been shown to be different in the two cases<sup>6</sup> and varies with the ratio of the concentration of these ions (see Table 1). These results were not due to a differential processing of the higher molecular weight  $\delta$ -crystallin protein to a lower molecular weight form at different concentrations of  $\text{Na}^+$  and  $\text{K}^+$ , because there was no transfer of radioactivity from the higher to the lower molecular weight band in preparations from lenses labelled for 3 h in the presence of ouabain in the ionic conditions described in Fig. 5b and subsequently incubated for 2 d with ouabain in the absence of protein synthesis (inhibited by  $10 \mu\text{g ml}^{-1}$  cycloheximide) in the ionic conditions given in Fig. 5f. The differential inhibition of synthesis of the non- $\delta$ -crystallin proteins was also eliminated by adjusting the concentration of  $\text{Na}^+$  and  $\text{K}^+$  in the lenses treated with ouabain (data not shown). Thus, intracellular  $\text{K}^+/\text{Na}^+$  ratios greater than 1 generally allowed

**Fig. 5** Scans of autoradiograms demonstrating the effects of  $\text{Na}^+$  and  $\text{K}^+$  on the synthesis of the higher and lower molecular weight polypeptides of  $\beta$ -crystallin. Embryonic chick lenses were cultured for 24 h in the absence (a) or presence (b–g) of  $1 \times 10^{-4}$  M ouabain and labelled with  $^{35}\text{S}$ -methionine for 3 h as in Fig. 3, except that the  $\text{Na}^+$  and  $\text{K}^+$  concentrations in the medium were varied. Approximately equal amounts of  $\delta$ -crystallin (1–2  $\mu\text{g}$ ) were examined by electrophoresis and autoradiography, and the  $\delta$ -crystallin bands were scanned with a Quick Scan Jr densitometer (Helena Laboratories). The  $\text{Na}^+$  and  $\text{K}^+$  values were (in mEq per kg  $\text{H}_2\text{O}$ ): a,  $\text{K}^+$ , 106;  $\text{Na}^+$ , 17; b,  $\text{K}^+$ , 3;  $\text{Na}^+$ , 151; c,  $\text{K}^+$ , 24;  $\text{Na}^+$ , 151; d,  $\text{K}^+$ , 72;  $\text{Na}^+$ , 151; e,  $\text{K}^+$ , 65;  $\text{Na}^+$ , 123; f,  $\text{K}^+$ , 65;  $\text{Na}^+$ , 51; g,  $\text{K}^+$ , 65;  $\text{Na}^+$ , 3. These values represent intracellular levels of these ions which, except for (a), were similar to the concentrations in the medium, since ouabain made the lens permeable to  $\text{Na}^+$  and  $\text{K}^+$ . The concentrations of  $\text{Na}^+$  and  $\text{K}^+$  in Ham's F-10 medium (a) are 151 mEq per kg water and 3 mEq per kg water, respectively. Deficiencies in  $\text{Na}^+$  were compensated by adding choline chloride to the medium (e–g).

the normal ratio of synthesis of the proteins in the two  $\delta$ -crystallin bands, while  $\text{K}^+/\text{Na}^+$  ratios less than 1 favoured the synthesis of the protein in the higher molecular weight band of  $\delta$ -crystallin (see Table 1 also). The only deviation from this behaviour that we have observed is presented in Fig. 5g, where an extremely low  $\text{Na}^+$  concentration permitted more synthesis of the protein in the lower molecular

weight  $\delta$ -crystallin band than would have occurred at a slightly higher concentration of  $\text{Na}^+$ . The alteration of  $\delta$ -crystallin synthesis, then, is not entirely a simple function of the intracellular  $\text{Na}^+/\text{K}^+$  ratio.

## Discussion

These present data have implications with respect to the biology and pathology of the lens and the control of protein synthesis in general at the cellular and molecular levels. Experiments with cultured rabbit lenses showed that a disturbance of the normal lens-vitreous relationship alters the normal intralenticular  $\text{Na}^+$  and  $\text{K}^+$  concentrations<sup>22</sup>. Our experiments extend this observation to the embryonic chick lens and in addition demonstrate that the altered intracellular  $\text{Na}^+$  and  $\text{K}^+$  levels are correlated with differential changes in protein synthesis. It is important to note, however, that we do not know if the differential inhibition of protein synthesis is controlled directly or indirectly by the intracellular levels of  $\text{Na}^+$  and  $\text{K}^+$ . The  $\text{Na}^+$  and  $\text{K}^+$  concentrations of the lens are known to change during cataractogenesis in other species<sup>2,15–20</sup>, so it is possible that there are associated disturbances in protein synthesis which, except for the cultured chick lens<sup>6</sup>, have not yet been observed. It is not known whether such putative changes in protein synthesis might have a causal role in the cataractogenic process in some cases. The cortical cataract formed in the embryonic chick lens cultured without its vitreous body is not due to the alteration in  $\delta$ -crystallin synthesis because the same disturbance in synthesis takes place in lenses treated with ouabain but the cortical fibres remain clear. The lens epithelia, however, become cloudy in the ouabain-treated lenses.

Deviations from the normal pattern of polypeptide synthesis, such as demonstrated here, may have consequences extending to higher levels of protein structure. Lens crystallins may be particularly susceptible to changes in their native structure since they are aggregates of polypeptides<sup>8,37,38</sup>. The alteration in synthesis of the ratio of the  $\delta$ -crystallin polypeptides does indeed result in new forms of the native protein, which is composed of four subunits<sup>39</sup>. These new species of  $\delta$ -crystallin, to be reported elsewhere, are still tetramers but consist of different combinations of  $\delta$ -crystallin subunits. Clearly alterations in the structure of native proteins may also affect their function.

Our earlier experiments involving cell-free translation of purified  $\delta$ -crystallin mRNA suggest that the control of  $\delta$ -crystallin synthesis by  $\text{Na}^+$  and  $\text{K}^+$  is mediated at the translational level<sup>14</sup>. Nonetheless, we have not excluded the possibility that one of the  $\delta$ -crystallin bands is post-translationally derived from the other. This would be consistent with the observation that the two bands have similar (although not necessarily identical) tryptic peptides<sup>14,40</sup>. A post-translational modification of either band into the other would have to be associated with translation, since the bands do not interconvert after they have been synthesised<sup>14</sup>. Differential translation has been reported for immunoglobulin mRNAs<sup>41</sup>, HeLa cell mRNAs<sup>42</sup> and viral mRNAs<sup>43–45</sup> in cells under suboptimal conditions for protein synthesis. Evaluation of the literature of many different systems<sup>28,46–49</sup> indicates that translational control of protein synthesis generally occurs at the level of chain initiation. Thus, if the present control of  $\delta$ -crystallin synthesis by  $\text{Na}^+$  and  $\text{K}^+$  functions at the translational level, it is likely that this involves regulation of initiation. This would represent a very interesting example of translational control of protein synthesis in view of the apparent homogeneity of  $\delta$ -crystallin mRNA<sup>50</sup>.

It has been pointed out previously that the intracellular concentrations of  $\text{Na}^+$  and  $\text{K}^+$  may affect the absolute amount of macromolecular synthesis, and thus perhaps growth, in eukaryotic cells<sup>24</sup>. In view of the present data,

one may further speculate that the control of specific protein synthesis during differentiation may be affected by differences in the intracellular levels of  $\text{Na}^+$  and  $\text{K}^+$ . For example, the relative proportions of crystallins synthesised change during differentiation of the lens and differ in different compartments of the lens<sup>8,10-13,51</sup>. Possibly gradients of ions within the lens play a part in this regulation of crystallin synthesis.

We thank Mr L. Merola for use of a flame photometer and advice on the determination of  $\text{Na}^+$  and  $\text{K}^+$ , Drs B. Chock and J. Jones for use of an atomic absorption spectrometer, Ms C. Kunkle and C. Harvey for typing the manuscript, and Drs J. H. Kinoshita, P. Zelenka, D. Beebe, R. Crouch and A. J. Coulombre for useful comments.

## Quasar-galaxy pairs and surface density of quasars

DISCOVERIES of radio-quiet quasars in the vicinity of galaxies<sup>1-5</sup>, sometimes with possible signs of interactions seem to contradict strongly the statistical analyses<sup>6-9</sup> on quasar-galaxy associations, which do not support the previous study<sup>10</sup> involving 3C quasars and bright galaxies. In each of these analyses<sup>6-10</sup>, the calculations used the surface densities of galaxies, because the surface density of quasars is poorly known, but it has been claimed<sup>11</sup> that the small angular separations are explicable by chance only if the surface density of quasars is much larger than believed. To test such an assumption we studied the problem by estimating directly the probabilities involved when adopting the most probable values of the density of quasars<sup>12,13</sup> at  $B \sim 19.0-19.5$ , that is,  $\mu \sim 3-5 \text{ (deg)}^{-2}$ .

The formula  $f_1(r) = 2\pi\mu r \exp(-\pi\mu r^2)$  gives the distribution of the angular separations ( $r$ ) between any galaxy and its nearest quasar. The characteristics of this distribution for different values of  $\mu$  are shown in Table 1 with the lower limit of the bilateral 95% confidence level range (column 4). The curves are shown in Fig. 1 with the lower limit taken from column 4 of table 1. For  $\mu \sim 3-5 \text{ (deg)}^{-2}$ , the curves suggest that quasars 3 arc min or more from a galaxy should not be called 'quasars near galaxies' as they occur by chance with more than 2.5% probability. Table 2 lists every radio-quiet quasar within 3 arc min of a galaxy (Arp, ref. 11) (MKN205 is excluded as a compact galaxy<sup>14</sup>). If we assume that Arp's search technique<sup>11</sup> yields quasars of the same nature as the other quasars (there is no evidence to the contrary<sup>15</sup>), for  $\mu = 3$ , nine such pairs would have been found if a search had been made using  $N = 386$  randomly selected quasars ( $P = 2.33\%$ ) and for  $\mu = 5$ ,  $N = 237$  ( $P = 3.80\%$ ). There is then no strong discrepancy with the presently known 140 radio-quiet quasars in the last

Reference Catalogue of Quasars<sup>16</sup>, since only two of these nine were not specifically searched for in the vicinity of galaxies. Moreover, 2 is less than the 3.3 and 5.3 expected pairs for  $\mu = 3$  and 5 respectively with  $N = 140$ .

Some other important effects are (1) two objects in Table 2 are not yet confirmed as quasars.

(2) We need a limiting magnitude for the galaxy, because, for every quasar, we could find a close foreground (or background) galaxy, however faint this galaxy is, if we were not limited by the sky brightness. Then we should exclude cases where very faint galaxies are involved, such as the 18 mag galaxy near 0846 + 51. Moreover, if quasars are associated with bright galaxies, as already suggested, how can they also be found at the distances of the faintest galaxies?

(3) Homogeneous samples of radio-quiet quasars<sup>7</sup> as well as the quasars recently<sup>17,18</sup> detected do not depart from a random distribution with respect to galaxies.

**Table 1** Distribution of the angular distances between quasars and galaxies if quasars are randomly distributed with a mean density  $\mu$

$\mu$ (deg) <sup>-2</sup>	Mean value (arc min)	Variance (arc min) <sup>2</sup>	Lower 95% limit (arc min)

†Blue variable star-like object.

(4) The choice of the galaxy may introduce two more observational selection effects in these small probabilities. Such probabilities are, in fact, the product of  $P_1 \times P_2$ ,  $P_1$  being the probability of finding a variable or blue stellar object in a particular location with respect to a galaxy<sup>19</sup>, and  $P_2$  the probability that this object is a quasar, equal to the number of pairs over the number of galaxies investigated. As the first step corresponding to  $P_1$  is omitted,  $P_2$  (a few per cent, according to ref. 11) is wrongly compared with the very small (but *a posteriori*) probability by chance ( $\sim 10^{-3}$ ) for such configurations, to prove the unlikelihood of the association; unfortunately the number of galaxies not investigated because of the absence of variable or blue stellar objects is inaccessible. A possible answer is that 'associated' quasars are associated only with galaxies having well-defined characteristics (morphological type, for example). Then the number of pairs involved here is much smaller and the existence of the excluded pairs can only be explained by chance, which proves then that close associations are not as rare as believed.

If a quasar lies within  $r$  arc min of a bright galaxy in the vicinity of which other fainter galaxies lie, (in a group for example, with a density  $\mu'$ ), then in  $P = 0.61 \mu' r^2$  of the cases, there will be another galaxy lying within  $r$  arc min of this galaxy and located nearer the quasar than the parent galaxy ( $P = 8.5\%$  if  $r = 10$  arc min and  $\mu' = 5(\text{deg}^{-2})$ ) and in  $P' = 1 - \exp(-\pi \mu' r^2)$  cases, another galaxy will lie within  $r$  arc min of the quasar ( $P' = 35\%$  with  $r$  and  $\mu'$  as above). In such cases the final angular separation will be

**Fig. 1** Distribution curves of the angular separations for different values of the density of quasars in  $(\text{deg}^{-2})$ . The dashed line indicates the locus of the lower limits of the 95% bilateral level range (see Table 1). a,  $\mu = 10$ ; b,  $\mu = 5$ ; c,  $\mu = 3$ ; d,  $\mu = 1$ .

calculated from the fainter galaxy instead of the bright one around which the search was made (cases of quasars associated with companion galaxies<sup>11</sup>). Such situations, which are not very rare according to the indicative probabilities found here, can artificially increase the number of close associations and reduce the angular distances in the same way.

It is difficult to evaluate quantitatively the result of such observational selection effects, except by a careful systematic search for radio-quiet quasars around galaxies. But if we take these effects into account, as well as the estimated density of quasars and the expected distribution of angular distances, the list of very close quasar-galaxy pairs and the values of the probabilities are not as impressive as before. So far as we can conclude, the small angular distances found between some radio-quiet quasars and galaxies do not disagree with the expected values corresponding to the most likely values of the surface density of quasars. These spectacular associations correspond only to the toes of the distribution of the angular separations and the discovery of such quasars seems to be due only to their exceptional location.

I thank D. Wills for helpful discussions and Dr H. Arp for communicating data before publication. This work was supported by a grant from the French Foreign Office.

## Pressure-induced changes in molecular conformation in liquid alkanes

LIQUID linear alkanes at room temperature and pressure exist in a mixture of molecular shapes. The *n*-heptane molecule, for example, has 13 possible distinct conformations with up to four gauche bonds distributed along its length. In the crystal, however, all the molecules assume the all-*trans*, straight chain shape. We have studied the conformations of chain molecules in the liquid state in various conditions using Raman scattering as a probe<sup>1</sup>. We have looked particularly at what happens to the shapes of linear alkane molecules subjected to high pressures in the liquid state. We speculated that as the pressure on a liquid of chain molecules was increased toward the freezing point that the chains might begin to straighten out. In fact, we found that an increase in pressure caused an increase in the number of gauche bonds, that is, pressure caused the molecules to become more globular.

Our interest in this investigation grew out of some recent discoveries concerning the conformation of linear polyethylene, a very long-chain molecule whose length can be as much as 1  $\mu\text{m}$  or more. Typically, polyethylene crystallised from the melt folds itself into straight chain segments tens of nanometres long, arranged side-by-side to form lamellae, with the segment axes perpendicular to the lamellar surface. The resulting material has relatively poor mechanical strength, presumably because

**Fig. 1** The CH stretching bands for heptane at 65 °C and pressures of *a*, 1 atm and *b*, 14.7 kbar. The peak at 2,880 cm<sup>-1</sup> disappears at high pressure as the molecules become more globular in shape.

it is held together mainly by Van der Waals forces between lamellae rather than by the carbon-carbon bonds of the polyethylene chain. On the other hand when polyethylene is crystallised at high pressure, ~ 5 kbar, the chains are extended to their full lengths in the solid<sup>2</sup> and, still more interesting, there is evidence that in the high pressure liquid before crystallisation the polyethylene chains exist in a 'nematic'-like state, an ordered liquid phase<sup>3</sup>. We wished to investigate this ordered phase and because the spectroscopy was more straightforward, decided to begin with short chain alkanes. Our results indicate that for the short chains the ordered liquid phase does not exist.

For heptane at room temperature and pressure the relative population of the all-*trans* conformer is about 15%<sup>4</sup>. The populations of other conformers can be calculated using the Boltzmann distribution, with each *gauche* bond requiring ~ 500 cal mol<sup>-1</sup> of energy. The greater statistical weight of the

**Fig. 2** Spectra of heptane as in Fig. 1 but for the lower frequency range. The intensities of the acoustic bands in the region 300–600 cm<sup>-1</sup> drop as the pressure rises, indicating that the populations of molecules in the all-*trans* conformation and molecules with one *gauche* bond are decreasing in favour of more highly kinked conformers.

*gauche* conformers overcomes the energy barrier and for liquid alkanes longer than nonane the *trans* population is small and spectroscopic observation of the *trans* species is extremely difficult.

In the Raman spectrum of the alkanes there are two frequency domains that are especially conformation sensitive: the high frequency C-H stretching bands and the low frequency acoustic bands. The high frequency region for heptane at 65 °C is shown in Fig. 1. The upper spectrum was taken at room pressure and shows a fairly sharp peak near 2,880 cm<sup>-1</sup>, the intensity and

**Fig. 3** Relative populations of molecules with one *gauche* bond, *a*,  $P_1$ , and with more than one *gauche* bond, *b*,  $P_{2-4}$ . The abscissa is the all-*trans* population,  $P_0$ , relative to its room pressure value,  $P_0^*$ . Pressure is increasing to the left therefore. Solid curves are theoretical predictions; open circles are data points.

sharpness of which has been shown to be proportional to the crystallinity and packing density of neighbouring chain molecules<sup>5</sup>. In the lower curve taken in the liquid at 14.7 kbar pressure this band has disappeared, indicating a probable reduction in lateral chain order.

Figure 2 shows the spectral range 200–1,500 cm<sup>-1</sup> for the same two pressures for heptane. Most of this spectral range is only slightly affected by the change in pressure and the band at 1,450 cm<sup>-1</sup> was used as an intensity standard. (The pressures were generated in a diamond anvil cell. The strong feature appearing in the high pressure spectrum near 1,300 cm<sup>-1</sup> is the diamond Raman band.) The frequency range 300–600 cm<sup>-1</sup> contains the acoustic modes which are affected quite strongly by pressure. These bands have been the subject of much study<sup>6,7</sup>. Model calculations have been made, and some of the normal modes for different conformations have been identified with these bands<sup>8</sup>.

The sharp peak near 309 cm<sup>-1</sup> is the so called 'longitudinal acoustic mode' (LAM) which is due to a vibration of the all-*trans*, TTTT, conformers along their chain axes. Its frequency is inversely proportional to the chain length. The band at 507 cm<sup>-1</sup> results from a molecule with a single *gauche* bond, TGTT, the band at 363 cm<sup>-1</sup> is due to the GTTT conformer, and the band at 396 cm<sup>-1</sup> is caused by a superposition of bands from a single *gauche* bond conformation, GTTT, and a double *gauche* conformer, TTGG.

Note that in the room pressure spectrum the all-*trans* band at 309 cm<sup>-1</sup> is by far the strongest peak although it accounts for only 15% of the molecular population. It seems

that as the molecules become more globular in shape, vibrations along the chain length have less effect on the polarisability. The intensities of bands for 3- and 4-*gauche* bond conformers are too weak to be detected.

It is apparent from Fig. 2b that all the bands in the low-frequency region decrease as the pressure increases with the LAM dropping more rapidly than its neighbours. This shows that the populations  $P_0$ , of the all-*trans* molecules, and  $P_1$ , of the single-*gauche* bond molecules, are decreasing in favour of  $P_{2-4}$ , the population of the 2-, 3-, and 4-*gauche* bond conformers.

We have developed a theory, generalised from liquid-crystal theory<sup>9</sup>, which predicts this behaviour. Our model consists of a dense gas of hard rods interacting only through excluded volume effects and Van der Waals attraction. The rods have no orientational correlations and are free to rotate end over end as in the case of an isotropic liquid crystal. Different conformers of heptane correspond to different species of rods, each with its own aspect ratio (length to breadth ratio) and energy (depending upon the number of *gauche* bonds). If the aspect ratio of a rod decreases, the excluded volume swept out as it tumbles is reduced and the translational entropy increases. If we calculate and minimise the Gibbs free energy for this model we find that rods with lower aspect ratios become more favoured as the pressure and density increase. This means that the molecules become more globular as the pressure rises.

Figure 3 shows the predictions for the rise of  $P_{2-4}$  and the drop of  $P_2$  as functions of  $P_0/P_0^*$  ( $P_0^*$  is the room pressure value of  $P_0$ ). Pressure therefore is increasing to the left in this figure. The agreement between theory and experiment is gratifying.

We have also investigated the conformational behaviour of hexane, octane, and hexadecane. The first two have behaviour similar to that of heptane. We recall that there is evidence for an ordered phase in a polyethylene liquid at high pressure. Since such a phase does not seem to exist in the short chain liquids one might expect to find a 'crossover' chain length above which the ordered phase could be found. Hexadecane at room pressure is made up almost entirely of *gauche* bonded conformers. We found that as the pressure was increased no significant change in the conformational population could be detected spectroscopically up to the freezing point for temperatures up to 165 °C. We conclude that either hexadecane is shorter than the 'crossover' length or that the ordered phase is inaccessible in this temperature range. We are continuing our investigation with other alkanes and polyethylene.

## Particle size analysis for machinery health monitoring

MONITORING the health, or condition, of machinery is a universally accepted way of achieving economy of use and preventing catastrophic failure. Wear debris analysis is a powerful method of monitoring oil-lubricated machinery and many techniques are used, such as spectroscopic oil-analysis<sup>1</sup>, magnetic plug and filter inspection<sup>2</sup>, ferrography<sup>3</sup>, and particle size analysis. Although this

Table 1 Particle size analysis

Sample no.	Gearbox hours	$n$	$b$ ( $\mu\text{m}$ )	$r$	Iron content ( $\text{mg l}^{-1}$ )
1	15	3.183	0.907	0.955	7.0
2	22	2.514	0.540	1.000	7.1
3	26.75	3.068	0.842	1.000	7.9
4	46.75	2.830	0.682	0.996	5.5
5	63.25	2.382	0.725	0.994	5.5
6	79.50	2.900	0.707	0.998	4.6
7	106.75	2.773	0.843	0.997	5.0
8	109.25	3.024	0.935	0.998	8.8
9	129.75	2.744	0.745	0.997	6.9
10	130.25	2.755	0.830	1.000	7.4

These values of  $n$ ,  $b$  and  $r$  were obtained with a lower size limit,  $d'$ , of 2  $\mu\text{m}$ ; this value corresponds to the limit of the sensor used.

last technique is frequently used for monitoring hydraulic fluids, where contamination levels are low, it has not been accepted as a means of monitoring relatively dirty systems such as gas turbines where other techniques are more efficient and easier to interpret. Here we show how the results from particle size analysis can be reduced to a simple indicator of the severity of wear; this indicator is related to spectroscopic oil analysis and shows promise as a method of monitoring the new generation of ultra-clean gas turbines.

The cumulative distribution of wear particles as a function of particle size can be fitted to the distribution function,  $P(d) = \exp - [b/(d-d')]^n$ ;  $P(d)$  is the probability of a particle being smaller than  $d$ ,  $d'$  is a lower particle size limit,  $b$  and  $n$  are the independent parameters which may be adjusted to fit the experimental results. This function is similar to that used by Rosin and Rammler<sup>4</sup> to describe the fineness of powdered coal. Taking logarithms twice

Fig. 1 Particle counts per 100 ml of oil for a, 2–5  $\mu\text{m}$ ; b, 5–10  $\mu\text{m}$ ; c, 10–15  $\mu\text{m}$ ; d, 15–25  $\mu\text{m}$ ; e, 25–60  $\mu\text{m}$ . The apparatus used works on the principle of light blockage in which particles passing through a cell interrupt a light beam incident on a photo-diode. As the particle passes through the cell it tumbles and the maximum projected area is detected and the particle is sized as having the diameter of a sphere with the same cross-sectional area.

**Fig. 2** Values of  $b$  (○), measured iron content (□), and calculated iron content (△) as a function of gearbox hours. The calculated iron contents were determined from the integral  $T\rho\int_0^{20}\pi d^3/24p(d)dd$  where  $p(d) = d P(d)/dd$ ,  $T$  is the total number of particles per litre and  $\rho$  is the density of steel. The integral was evaluated using Simpson's rule.

yields  $\ln[\ln(1/P(d))] = -n\ln(d-d') + n\ln b$ . Thus a plot of  $\ln[\ln(1/P(d))]$  against  $-\ln(d-d')$  should be linear if the distribution function is applicable to the experimental results. From the form of  $P(d)$  we see that 36.7% of the particles will be smaller than  $b+d'$ . Since it is generally accepted that an increase in the relative number of large particles is an indication of an increasing severity of wear, it may be possible to use  $b$  as an indicator of the severity of wear.

Ten oil samples from a helicopter gearbox test-rig were used to test this theory. The particle sizes were analysed with a 'Hi-Ac' automatic particle size analyser; the iron contents were measured using an X-ray fluorescence spectrometer. The particle size analysis for the 10 samples is shown in Fig. 1. The values of  $n$ ,  $b$  and  $r$  (the regression coefficient) obtained by fitting the particle counts to the distribution function, and the measured iron contents are given in Table 1.

Figure 2 compares the values of  $b$ , the measured iron contents and the calculated iron contents. The close agreement between the trends in  $b$  and the measured iron content is striking and shows that  $b$  can be used as an indicator of wear. A comparison of Figs 1 and 2 illustrates how this analysis has simplified the somewhat complicated results of particle counting.

Figure 2 also shows the good agreement between the trends of the measured and calculated iron contents. Since wear particles are rarely spherical the expression for the iron content would be expected to be an overestimation. The good agreement actually observed is presumably due to the fact that particles smaller than  $2 \mu\text{m}$  are ignored by the particle counter.

I believe that this new interpretation of particle size analysis may well become an important technique for machinery health monitoring, especially as the trend towards improved filtration reduces the relative sensitivity of spectroscopic oil analysis.

Further details of this analysis as well as the relationship between particle size analysis and direct reading ferrography will be published elsewhere. I thank Mr P. Gadd of the Naval Aircraft Materials Laboratory for the particle size analysis.

## Intensification of the Gulf Stream after the winter of 1976-77

THE eastward volume transport of the Gulf Stream south of New England varies within a wide range. Within a triangle whose apex is at Bermuda and whose base extends from Cape Hatteras to Cape Sable, Nova Scotia, there have been 32 reliable oceanographic sections made across the Stream between 1932 and 1968. Geostrophic volume transports for these sections, computed relative to 2,000 m, are shown in Fig. 1. This 2,000 m surface is necessary if any seasonal change in transport is to be detected; only 10 of these sections reach to the ocean bottom ( $\sim 4,500 \text{ m}$ ), and these were all made between April and August. These results tend to confirm an earlier suggestion<sup>1</sup> that the Gulf Stream is strongest in late winter and weakest in late autumn; this was attributed to the strengthening of the zonal winds in the winter. More recently, I have postulated a different mechanism for this annual variation in transport. The two most intense ocean currents, the Gulf Stream and the Kuroshio, are found on the western side of northern hemisphere oceans. These oceanic regions are visited throughout the winter by frequent outbreaks of frigid polar continental air. As a result of these outbreaks, very deep mixed layers are formed immediately south of these currents in late winter. The greatest thermocline depths are always found directly beneath the most deeply mixed layers, and it is primarily the variations in thermocline depth which account for the variations in computed transport shown in Fig. 1; the deeper the thermocline south of the Stream, the larger the transport. I suggest that the Gulf Stream receives a new charge of energy at the end of each winter due to this deepening of the thermocline. Here I discuss how the cold winter of 1976-77 influenced the Gulf Stream transport.

The temperature distribution in the western North Atlantic can be seen in the first more-or-less meridional section across the Sargasso Sea made by Thomson<sup>2</sup> in HMS Challenger. This section (Fig. 2) passed across the Gulf Stream in May; spring warming had started up at the sea surface above the deep, nearly mixed layer immediately south of the Gulf Stream. The Gulf Stream System is an asymmetric anticyclone. The narrow, intense eastward flow of the Gulf Stream itself takes place between

**Fig. 1** Computed geostrophic volume transports for sections in the Bermuda - Nova Scotia - Cape Hatteras triangle: ●, 32 sections made between 1932 and 1968; ○, sections made before and after the winter 1974-75; △, between Researcher stations 6 and 33 in April 1977. All transports are relative to 2,000m and are plotted against month.

Challenger stations 42 and 44. The slower and much wider return flow toward the west takes place between stations 42 and 24, augmented by a further westward flow through the Caribbean Sea south of station 24. The maximum top-to-bottom transport of the anticyclone has been estimated to be about  $150 \times 10^6 \text{ m}^3 \text{ s}^{-1}$  (refs 4, 5) of which only about  $30 \times 10^6 \text{ m}^3 \text{ s}^{-1}$  pass through the Caribbean. Tropical surface water from the Caribbean can be seen as the 'warm core' at Challenger station 43. Superimposed on the anticyclone one can infer a shallow, meridional circulation in which excess  $18^\circ \text{C}$  water (ref. 6), formed at the end of the winter, flows south at the 300 m level and surface water is advected north to replace it. This process does not directly affect the Gulf Stream transport.

It can be seen (Fig. 2) that the thermocline is, in fact, deepest in the centre of the anticyclone beneath the thickest part of the lens of  $18^\circ \text{C}$  water. To the north, the thermocline rises abruptly across the Gulf Stream, and the lens of  $18^\circ \text{C}$  water disappears abruptly. To the south the thermocline rises gradually and the lens of  $18^\circ \text{C}$  attenuates gradually.

It is difficult to test hypotheses in the ocean, but an attempt was made during 1974-75 to observe the formation

of  $18^\circ \text{C}$  water and its possible effect on the anticyclone. An extensive oceanographic survey was made in October and November of 1974 and repeated in March 1975. No deep mixed layers were formed, and the  $18^\circ \text{C}$  water was not renewed by the atmosphere. Research ship cruises must be planned a year or two ahead of time, hence observers interested in short-scale climatic changes must simply take their chances. Precise calculation of the heat flux from ocean to atmosphere cannot be made at present since there is a three or four year lag before the necessary marine meteorological data can be obtained on magnetic tape, but the winter of 1974-75 was exceptionally mild over the northwestern Sargasso Sea.

The winter of 1976-77, however, has been exceptionally cold in the eastern US. The surface atmospheric pressure map for mid-January to mid-February 1977 is drawn in Fig. 3. It is marked by a shift of the Icelandic low towards Newfoundland and a retreat of the Azores-Bermuda high towards the east. This was accompanied by a flow of continental polar air across the northwestern Sargasso Sea. This pattern was present much of the winter but broke up completely in March 1977.

I was invited aboard the Ocean Survey ship Researcher in April 1977 to investigate the effect of this remarkable winter on the  $18^\circ \text{C}$  water and its influence, if any, on the Gulf Stream transport.

Again, precise heat flux computations cannot be made at present, but the contrast between the mixed layer depths after the mild winter and the severe winter was vivid. Late winter temperature-depth and dissolved oxygen-depth curves for neighbouring oceanographic stations near the southern edge of the Gulf Stream are shown in Fig. 4. Knorr station 577 ( $34^\circ 31' \text{N}$ ,  $72^\circ 31' \text{W}$ ; 10 March 1975) has a mixed layer only 175 m deep. A faint inflexion can be seen in the  $18^\circ \text{C}$  water at 300 m. This is probably a relic of a previous winter when renewal of  $18^\circ \text{C}$  water by the atmosphere did take place. The concentration of dissolved oxygen at 300 m was 4.45 ml per l (81% of saturation), indicating that biological consumption of oxygen had been going on for some time. Below this inflection the temperature gradient increases rapidly to  $1^\circ \text{C}$  per 50 m, the normal value for the thermocline in the Sargasso Sea. The depth of the  $10^\circ \text{C}$  isotherm, a commonly used index of thermocline depth, is 815 m.

The upper 200 m of Researcher station 33 ( $34^\circ 30' \text{N}$ ,  $71^\circ 18' \text{W}$ ; 12 April 1977) is composed of 'warm core' Gulf Stream water, but the rest of the top 600 m consists of newly formed  $18^\circ \text{C}$  water with oxygen values of about 5.1 ml per l (96% of saturation). The thermocline is much deeper: the  $10^\circ \text{C}$  isotherm lies at a depth of 1,020 m,

**Fig. 2** Temperature section from St Thomas, Virgin Islands, to Bermuda to New York, made from HMS Challenger in spring, 1873.

deeper than at any of the earlier stations used for the computation of Gulf Stream transport (Fig. 1).

Computed volume transports for the two sections made before and after the mild winter of 1974–75 are also plotted in Fig. 1. While the late winter section ( $62 \times 10^6 \text{ m}^3 \text{ s}^{-1}$ ) is slightly higher than the autumn section ( $57 \times 10^6 \text{ m}^3 \text{ s}^{-1}$ ), these two sections give the two least volume transport figures ever computed, relative to the 2,000 m surface, in this area. Researcher station 33 has been paired with the nearest station north of the Gulf Stream (Researcher station 6;  $37^\circ 46' \text{N}$ ,  $72^\circ 00' \text{W}$ , 1 April 1977), and the computed volume transport between them,  $95 \times 10^6 \text{ m}^3 \text{ s}^{-1}$ , has also been plotted in Fig. 1. It is the largest volume transport ever computed for the Gulf Stream.

With reservations, these data add credence to my proposed mechanism of oceanic anticyclogenesis<sup>2</sup>. The

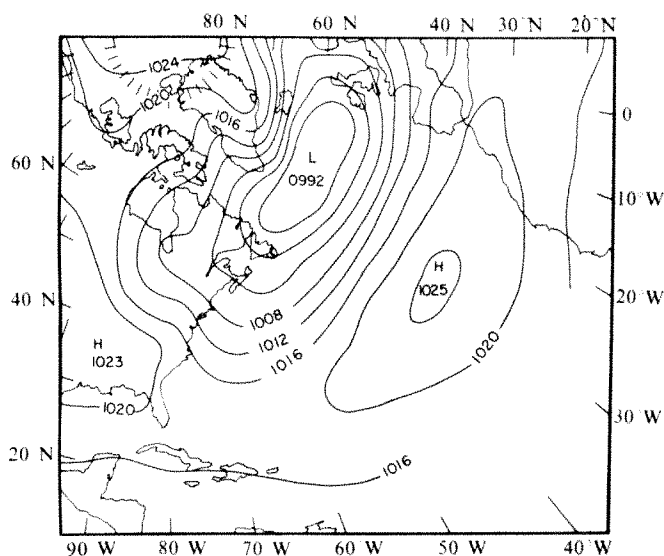

Fig. 3 Average surface atmospheric pressure for the period mid-January to mid-February 1977.

main reservations are these: Researcher was equipped with expendable bathythermographs that recorded the temperature down to 760 m. Thus it was possible to place station 33 in the exact centre of the region where the mixed layer was deepest and the thermocline was deepest. Knorr was similarly equipped during the two cruises which showed the lowest volume transports (Fig. 1) and these low figures are undoubtedly true. These sections were made, however, in a different longitude ( $64^\circ 30' \text{W}$ ) on the Nova Scotia side of the Hatteras–Bermuda–Nova Scotia triangle where the current (in the upper layers) may be weaker<sup>5</sup>. Also, the areas where the deepest mixed layers were found were not very wide. Such deep mixed layers could easily have been missed by earlier observers. It is further possible to assume that Researcher station 33 was in the centre of a small, local anticyclone independent of the Gulf Stream. Nevertheless, it seems that the Gulf Stream gained strength after the cold winter of 1976–77. I attribute this to deep winter overturn. It is hard to see how this intensification can have been due to wind-stress alone in view of the air-flow pattern indicated by surface atmospheric pressure (Fig. 3). The theoretical Gulf Stream transport corresponding to the mean wind-stress field is only  $23 \times 10^6 \text{ m}^3 \text{ s}^{-1}$  (see ref. 7). Thus the gross variability in baroclinic transport in the upper half of the Gulf Stream ( $57$ – $95 \times 10^6 \text{ m}^3 \text{ s}^{-1}$ ) is nearly double the total mean theoretical wind-driven transport.

Masuzawa<sup>8</sup> has shown a meridional section across the Kuroshio system made in January 1967 in which deep

Fig. 4 Temperature–depth (solid lines) and oxygen–depth (dashed lines) curves for stations made south of the Gulf Stream in late winter 1975 (○) and early spring 1977 (△).

mixing may have contributed to the depression of the thermocline south of Japan. This section also shows the equatorward spreading of subtropical mode water, the northwest Pacific analogue of  $18^\circ \text{C}$  water. McCartney<sup>9</sup> has discovered that a similar process takes place on the equatorward side of the Antarctic Circumpolar Current. It seems that the greatest current systems in the world oceans are accompanied by deep mixing on their equatorward sides, and it is possible that they derive the greater part of their energy from this process.

## Manganese-rich particulate matter in a coastal marine environment

PARTICULATE matter in the waters of the Gulf of St Lawrence, a major marginal sea, contains as much as 16,500 p.p.m. manganese. This is comparable with the levels of manganese found in deep-sea sediments<sup>1</sup>. Here we show that it is possibly a related phenomenon. Suspended particulate matter was collected by filtration on  $0.4\text{-}\mu\text{m}$  Nucleopore filters on a series of six stations along the axis of the Laurentian Trough. The samples were digested in a Teflon bomb with a mixture of aqua regia and hydrofluoric acid, and analysed by atomic absorption spectrophotometry<sup>2</sup>. Figure 1 shows a typical vertical profile of the concentration of suspended particulate matter and its content of manganese. The manganese content increases

rapidly with depth to a maximum value of 16,500 p.p.m. at 40–120 m above the bottom. The profiles are similar for the two cruises.

Resuspension of manganese-rich bottom sediment, and diffusion of dissolved manganese out of the sediment with subsequent precipitation in the water column, are two mechanisms which may produce manganese-rich particulate matter. Figure 2 shows that a manganese-rich surface layer, only a few millimetres thick, covers a sediment which otherwise is uniformly low in manganese. Higher concentrations of particulate matter near the bottom than at intermediate depths exist throughout the deep parts of the Gulf of St Lawrence<sup>3</sup>, indicating that resuspension of bottom sediments is an active mechanism<sup>4</sup>. But, the manganese content of the near-bottom particulate matter is higher than in the upper 1 mm of the sediment (by a factor of 4 to 5). Resuspension as the sole responsible mechanism requires, therefore, that the particulate matter retained in suspension—that is the slow settling components of the resuspended sediment—contain much more manganese than the bulk sediment. This possibility cannot be confirmed, however, because there are no data available on the manganese content of these sediments as function of settling rates.

The thinness of the manganese-rich sediment layer, and by inference the oxidised zone, indicates that manganese dissolved in the pore water would only have to diffuse a short distance to pass from the reduced zone to the water column. Subsequent precipitation would then result in manganese-rich particulate matter; this mechanism has been proposed by Evans *et al.*<sup>5</sup>. Graham *et al.*<sup>6</sup> have shown that diffusion of dissolved manganese out of sediments is fast enough to be a major factor in the manganese balance in Narragansett Bay.

Some of the manganese-rich particulate matter may reach the seaward-moving layer of the water-column by vertical mixing and advection, and ultimately find its way to the open ocean. This is supported by the data of Bewers and Yeats<sup>7</sup>, which show that whereas 93% of the input of particulate matter to the Gulf of St Lawrence sediments internally, only 47% of the manganese input is lost in this

**Fig. 1** Vertical distribution of the concentration and manganese content of suspended particulate matter (SPM) on a deep station in the Laurentian Trough, Gulf of St Lawrence (48° 42.2' N, 68° 39.5' W). *a*, Manganese in May; *b*, manganese in September; *c*, SPM in May; *d*, SPM in September.

**Fig. 2** Vertical distribution of manganese in a sediment core from the Laurentian Trough, Gulf of St Lawrence (48° 40.8' N, 68° 38.8' W). The core was taken with a box corer, subsampled immediately, and analysed by the method of Rantala and Loring<sup>17</sup>.

way. As the exported manganese is predominantly in particulate form, it seems that the exported particulate matter is enriched in manganese. Furthermore, the existence of individual particles, greatly enriched in manganese, has recently been demonstrated in suspended matter from the Atlantic Ocean<sup>8</sup>. Using scanning electron microscopy and an electron probe, it was shown that the particulate matter is composed of several phases of different manganese concentrations, so that the bulk composition is controlled by the relative abundance of these phases. Thus, manganese was enriched to about 10 times the normal level in clay particles that make up 10% of the total clay.

If production and export of manganese-rich particulate matter occurs generally in the coastal zone, it will have interesting implications for oceanic geochemistry. Manganese and other trace elements are not homogeneously distributed in deep-sea sediments. Thus, the highest concentrations are not found in clays from the abyssal plains adjacent to the continents, but from elevated areas remote from the continents. To explain this, Turekian<sup>9</sup> distinguished between two sediment transport mechanisms: bottom transport and deposition, and eupelagic deposition. The continentally remote hilltops contain material derived from the higher parts of the water column, that is the eupelagic components, and the abyssal plains adjacent to the continents contain the bottom transported components in addition. If very fine particles, rich in the critical trace elements, were transported by the surface layers of the oceans, then a uniform 'rain' of trace elements in particulate form would occur over the entire ocean. The bottom transported components would act as a diluent, causing the lower levels of trace elements observed in sediments adjacent to the continents.

The major problem with the theory is the origin of manganese-rich particles. Turekian<sup>9</sup> suggested that the fine particles could either be manganese oxide produced during the weathering of rocks, or small particles with high specific surface area which had absorbed the critical trace elements during stream transport. The difficulty with this is the implication that the removal of trace elements such as Ni, Co and Mn from seawater is of secondary importance to their removal in the river environment. The removal

of trace elements from seawater, and the maintenance of steady-state conditions, is thought to occur through scavenging by particulate matter settling through the water column<sup>10,11</sup>, and in particular by hydrous oxides of manganese in view of their high capacity for absorbing metal ions<sup>12</sup>. As Turekian<sup>9</sup> has pointed out, it is doubtful if particles transported by streams, be they manganese oxide or clay particles, are efficient scavengers of trace metals from seawater. As the concentrations of most trace elements are as high in streams as in seawater, trace elements would most likely have been absorbed to capacity on the stream particles. The higher sodium content of seawater would tend to inhibit further adsorption of trace elements from seawater, if not actually cause their release.

A marine, rather than river, origin of manganese-rich particles would remove this difficulty. These particles, with their content of freshly precipitated manganese oxide, would be the ideal scavenger, helping maintain the low concentrations of dissolved trace metals in seawater.

Another implication comes from massbalance calculations which involve manganese. Elderfield<sup>13</sup>, in a recent attempt to draw up a budget for oceanic manganese, concluded that the rate at which rivers supply dissolved manganese to the ocean is about an order of magnitude less than the rate at which non-lithogenous manganese accumulates in pelagic sediments. Hence, other significant sources of non-lithogenous manganese must exist.

One such source, if liberated by near-shore diagenetic processes, could be the non-lithogenous fraction in river-borne detritus, that is absorbed and complexed manganese and manganese oxide coatings. The riverborne detritus, of which some 95% never reaches the open ocean<sup>14</sup>, could then be considered a reservoir for manganese, available for remobilisation. The annual input of riverborne detritus to the marine environment is about  $2 \times 10^{16}$  g (ref. 15). If, from the total manganese carried by the detritus (estimated at an average of 4,300 p.p.m. (ref. 16)) as little as 50 p.p.m. were on average remobilised, that alone would amount to a flux of  $10^{12}$  g yr<sup>-1</sup>. This is an order of magnitude higher than the dissolved manganese supplied by the rivers, indicating the potential significance of this source.

## Equilibrium concentrations of methylmercury in Ottawa River sediments

MOST of the mercury (up to 97%) found in aquatic systems is associated with bed sediments<sup>1</sup>. Fish, invertebrates and plants contain only 0.02% of the total, though they contain a high proportion of organic mercury. Field surveys show that the proportion of organic mercury in the sediments range from

0.1 to 2.1%<sup>2–6</sup>. Jacobs and Keeney placed river sediments mixed with inorganic mercury in the Wisconsin and Fox Rivers<sup>7</sup>. After 12 weeks exposure to the natural environment the concentration of methylmercury in the sediments was only 3%. This concentration of methylmercury was attained within 4 weeks after sediments were placed in the bottom of the rivers. This indicated that the processes of methylation and demethylation of mercury were in equilibrium in these environmental conditions within 4 weeks. But no experiments were conducted to show the degradation of methylmercury in sediments. After the methylation study by Jensen and Jernelöv<sup>8</sup>, many investigations into methylmercury production by micro-organisms in bed sediments have been carried out. Little attention, however, has been paid to the ratio of methylmercury to the total mercury existing in the sediments. Spangler *et al.* observed degradation of methylmercury in mixed cultures from sediments<sup>9</sup>. The degradation reached 50% within 5 d, they also found methylmercury degradation in sediments. But detailed information about the sediments was not available and results fluctuated wildly. We do not know the total amount of methylmercury existing in all components of the systems, including fish, invertebrates and plants as well as various types of bed sediments. Here we use methylmercury equilibrium concentration levels in the Ottawa River sediments to estimate the amount of methylmercury in various types of bed sediment where detailed information of total mercury concentrations (total mercury estimation 31 kg) and types of sediment is available. Two ways (methylmercury production and degradation) of reaching equilibrium were observed during 50 d in identical environmental conditions.

Three types of fresh sediments from the study section of the Ottawa River were spiked with either radioactive mercuric chloride or methylmercuric chloride at a level of 1.00 p.p.m. The three sediments were: (A) main stream sediments, (B) north channel sediments, and (C) wood-chip sediments which were located in the north channel but just down-stream of the pulp and paper company. Original total mercury concentrations in the three types of sediments were determined by atomic absorption spectrometry as 17, 23 and 1,600 p.p.b., for type A, B and C sediment, respectively. Therefore, final concentrations of total mercury in type A, B and C sediments were 1,017, 1,023 and 2,600 p.p.b. More detailed information about these sediments is given elsewhere<sup>10</sup>.

Because no isotopic exchanges were observed between organic and inorganic mercury under natural environmental conditions and in these mercury concentration ranges<sup>11</sup>, it was possible to consider that increase or decrease of radioactive methylmercury in sediments was caused by methylation or demethylation not by simple isotopic exchanges. Organic contents of these sediments (A, B and C) were 0.35, 0.84 and 59.2%, respectively. The sediments were placed in the dark at 20° C and closed to prevent a loss of moisture as well as of mercury from the sediments.

Thin layer chromatography (TLC) and atomic absorption were used to determine the quantities of the various chemical forms of mercury, mainly mercuric and methylmercuric as well as the total mercury in sediments. A modification was made to extract various forms of mercury from sediments using 0.1% dithizone–benzene solution. Over 98% of the mercury from sediments was recovered using this modified method. *R<sub>f</sub>* values in the thin layer chromatography for mercuric and methylmercuric forms, respectively, were 0.36 and 0.66 using water–methylcellulose as the developing solvent. A portion of the mercuric and methylmercuric bands as well as other bands containing mercury were separated from the TLC sheet and were counted for radioactivity. All samples were analysed in duplicate.

Surprisingly, methylmercury in cleaner sediments (type A, main channel sediments (sands)) degraded more rapidly into inorganic forms, Fig. 1. Within 25 d, 80% of methylmercury was broken into inorganic forms in the sand sediments, whereas, only 14% of methylmercury was converted into

Fig. 1 Equilibrium concentration of methylmercury in Ottawa River sediments. Sediment A is shown by squares, B by circles and C by triangles, closed symbol, start from mercuric chloride only; open symbol, start from methylmercuric chloride only.

inorganic forms in the organic sediments (type C) during the same period. Sediments which were mixed with an inorganic form of mercury increased their contents of methylmercury with time. For highly organic contaminated sediments (type C, wood-chip sediments) the portion of methylmercury was 7.4% and for cleaner sand (type A, main channel sediments) the portion was only 0.1% after 25 d. The difference in final methylmercury concentration between sand (A) and wood-chip (C) sediments is probably a result of the different rates of formation and decomposition of methylmercury in these sediments. That is, the wood-chip sediment forms methylmercury more rapidly and also decomposes methylmercury more slowly than does the sand sediment. During the 50-d experiments, an average of 1.3% of mercury escaped from the system.

Methylmercury concentrations in each of the three types of sediments converged to an equilibrium concentration level from both directions starting with mercuric chloride and methylmercuric chloride, with an increase of time, Fig. 1. From the results, the equilibrium concentration levels were estimated for sediments A, B and C as 0.2, 2.3 and 12.1%, and the time to attain the equilibrium concentration was estimated as 3, 3, and 6 months, respectively.

Applying this methylmercury information to Ottawa River sediments, amounts of methylmercury were calculated as 1,200 g for the study section of the Ottawa River in 1972. In this calculation, the 4.88 km by 1.5 km section was divided into five regions depending on the type of bed sediments existing in the section of the river. The amounts of biomass in the study section were 5.3, 11.1, and 65.4 tons (wet) for fish, invertebrates, and plants, respectively. This biomass contained only 6.0 g of total mercury. In other words, bed sediments contained 200 times more methylmercury than those in biomass, even assuming all of the mercury in biomass was

methylmercury. Of course, the accuracy of this calculation of methylmercury in the sediments was not as high as that for the estimation of the total mercury in biomass in the study section. The calculation clearly showed, however, that methylmercury existing in the sediments was higher by at least two orders of magnitude, than those in the biomass. This further indicates that a detailed study must be directed toward mercury in bed sediments to understand and control, effectively, mercury pollution in aquatic systems.

We thank Mr J. Trepanier, Mrs E. Javorsky and Mr M. Y. Pinard for their contribution.

## Origin of coal basins by salt solution

WILLISTON Basin of North America, one of the world's largest brown coal basins with diameter 550 km, is interpreted as an effect of regional solution of up to 150 m thickness of Devonian salt. The Late Cretaceous-Tertiary salt removal from the buried Elk Point Evaporite Basin (Middle Devonian) has resulted in sufficient collapse subsidence to be structurally reflected in the 2,000–3,000 m of overlying Palaeozoic and Mesozoic stratigraphic column. The Palaeocene coalfields are topset to Late Cretaceous delta lobes developed within salt solution troughs. This syndepositional mechanism for coal basin formation has not previously been recognised.

The most extensive coal basins were emplaced marginal to the Roncott Platform<sup>1-3</sup>, a major salt salient into the 2,500 km<sup>2</sup> of complete salt removal across southern Saskatchewan (Figs 1 and 2). Ground water circulation believed to have caused the salt solution is attributed to flow under hydraulic head from the nearby Rocky Mountains which were emerging to the southwest. Initially, it was directed along vertical planes associated with rejuvenated Precambrian lineaments, which are related to a possible plate boundary<sup>4</sup> that trends across western South Dakota and eastern Montana and traceable into south-central Saskatchewan as the salt solution axes flanking the Roncott Platform.

The Palaeocene coal measures are coal-bearing bodies that are topset to the Cretaceous delta lobes. Wood Mountain-Willow Bunch complex is the largest<sup>5</sup> of the coalfields (Fig. 2). Its several depositional troughs are along the western margin of the Roncott Platform (Figs 2 and 3). The thicker parts of seams overlie anomalous negative troughs on the Late Cretaceous structural surface, which themselves partially represent syndepositional clastic thickening trends. The coal seams of the Wood Mountain and Willow Bunch coal basins have their thicker parts superimposed. These are in turn vertically above the Late Cretaceous delta lobes' axial lengths. Without the underlying solution subsidence any thick peat accumulation associated with temporary mobile axes would not be preserved

**Fig. 1** Isopachous map of the Prairie Evaporite Formation (Devonian) salt and potash beds in the Elk Point Evaporite Basin across western Canada. Contour interval is 75 m. The salt beds to the south-east were leached, resulting in evaporite-solution brecciation of superjacent strata, especially during the Late Cretaceous to Lower Tertiary. The resulting extensive collapse subsidence over this zone was reflected up the 2,000–3,000 m stratigraphic column during the emplacement of Williston Basin's deltaic topset coal basins, whose preservation was assured within the subsidence troughs. The best developed coal basins were emplaced marginal to the Roncott Platform, a salt salient that extends northwards from northeastern Montana into the leached zone (Fig. 2).

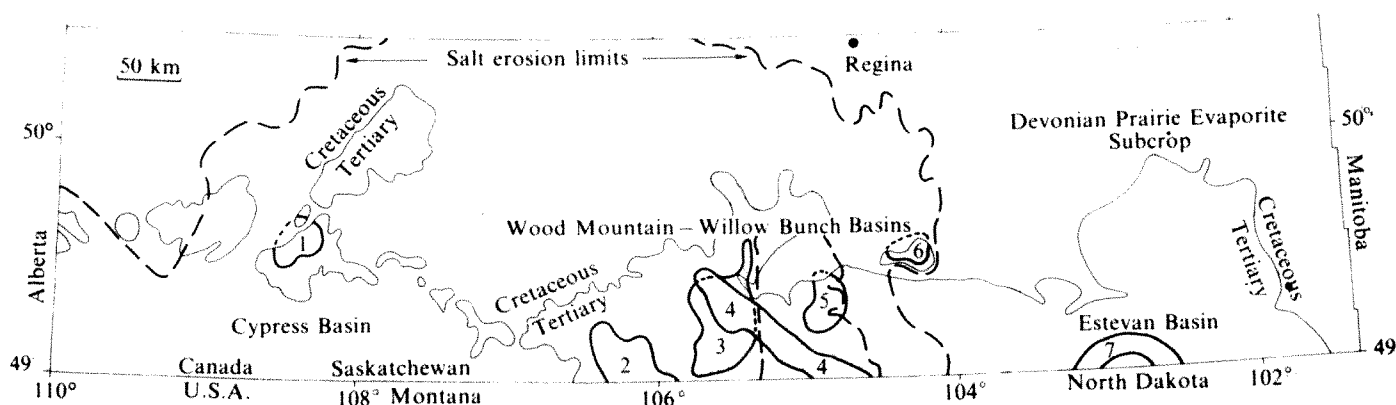

in the record. This phenomenon of coal basin genesis is well illustrated by deposition within the Coronach Trough, marginal to the western flank of the Roncott Platform (Fig. 2). There are six major seam groups in the Ravenscrag Formation of the Coronach Trough. The thickest seam of the 80–120 m coal measures in the trough, as well as in the formation, is the Hart seam. Its thickened trend, the 3–10 m thickness isopach interval, is a north-south subcrop belt, 8–24 km wide, that parallels the 65 km length of the Roncott Platform salt subcrop erosional edge north of the International Boundary (basin 3, Fig. 2). The Hart seam thins eastward in the subcrop along a broad front paralleling this salt erosional edge such that the

thinned depositional margin of the seam basin and the Roncott Platform western erosional edge coincide in the vertical succession along most of its length. Where the seam encroaches on to the salt platform subcrop zone, it is less than 1-m thick. All seams in the coal measures that are of sufficient thickness to be correlative between boreholes in the subcrop have their axes of maximum thickness superimposed, paralleling the Roncott Platform erosional margin and vertically along the maximum thickness trend of the Hart seam. They similarly thin eastward along a broad front as they encroach the salt substrate. The uppermost seam group of the Willow Bunch Basin, the 4–7 m thick seams of the Willow Bunch group (basin 4, Fig. 2) are exceptional in that they transect the Roncott Platform; their deposition axes are oblique to the Coronach Trough subsidence. The isopachous trends of Willow Bunch seams demonstrate the markedly diminished influence of salt solution subsidence emplacement and the assertion of the regional cratonic southeastern subsidence in the syntectonic sedimentological framework.

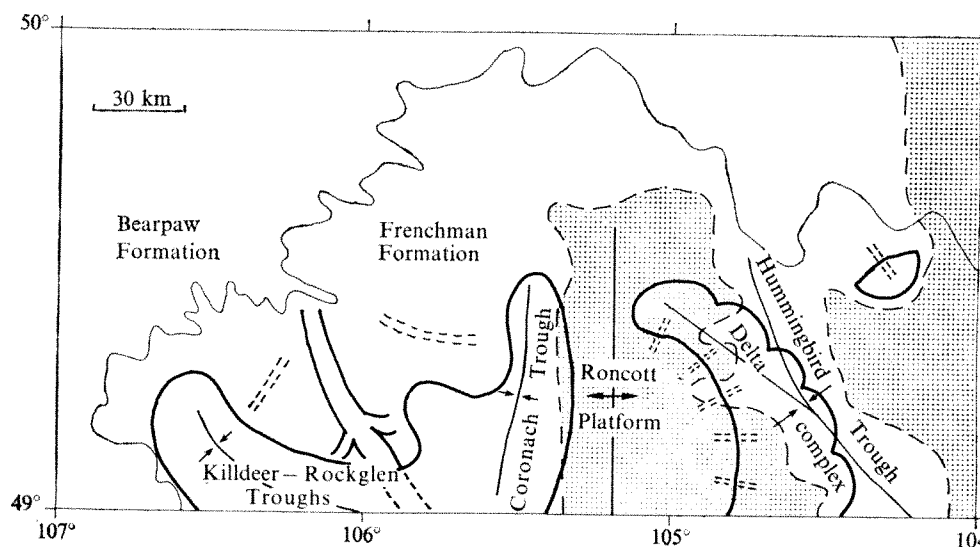

The salt solution subsidences of the Killdeer–Rockglen and Coronach Troughs (Fig. 3) were contemporaneous with the final recession of the Bearpaw sea. They favoured the fixation of vertically accreting Late Cretaceous deltaic lobes within a Catskill-like<sup>6</sup> muddy shoreline that transgressed over the sea. The main delta body, approximately 100 km across, extends south of the International Boundary beyond the study area (Fig. 3), and is comparable in size to the largest of deltas observed in the sedimentary record world-wide. The delta lobe accretion along subsidence axes inhibited lateral progradation and developed the Palaeocene coal measures as topset beds: the margins of the largest seam basins coincide with the subcrop extent of the late Cretaceous lobe. This sequence is repeated with modification eastward into the Hummingbird Trough along the eastern margin of the Roncott Platform (Fig. 3). Sufficient but incomplete removal of evaporite beds contemporaneous with the Late Cretaceous continental transgression across the eastern Platform developed a series of coalesced 5–10-km diameter lobes (Fig. 3) that encroached the western limb of the Hummingbird Trough. The relatively small Bengough coalfield (basin 5, Fig. 2) in the overlying Palaeocene thus is situated on this semi-stable Roncott salt platform area, but its thick seams do not laterally extend into the axial area of the Hummingbird Trough. This may be due to unfavourable subsidence for accumulation and preservation of peat sections.

The few major intracratonic deltas studied in the ancient sedimentary record, for example, the Upper Cretaceous delta of

**Fig. 2** The late Tertiary and Pleistocene drift blankets the unconformably Late Cretaceous to Early Tertiary bedrock surface on the northern limb of the Williston Basin, southern Saskatchewan. Most of the Palaeocene coal basins of this borehole exploration area are emplaced within salt solution subsidence zones: Cypress (1) Wood Mountain (2) and portions of the Willow Bunch (3–6) Basins. The lower coal measures of the Coronach Trough (3) are emplaced to offset to the paralleling western margin of the Roncott Platform's rigid salt substrate, whereas the Bengough coalfield (5) is developed with the partial solution subsidence of the eastern half of the salt structure. Minor coal basins (6) are emplaced within embayments into the salt substrate along the eastern Hummingbird Trough (Fig. 3) contact with the regional salt substrate. The stratigraphically high Willow Bunch seam group basin (4) is the least affected by the solution subsidence, and transects the subjacent solution axis. Likewise, the equivalently young Estevan Basin (7) coal measures develop with the assertion of cratonic subsidence as the dominate syndepositional genesis of coal basins in place of solution subsidence.

**Fig. 3** Emplacement of the Late Cretaceous delta lobes along salt solution subsidence axes within the Frenchman formation. These lobes persisted in the vertical succession as topset Palaeocene coal basins. Extensive progradation of the main lobe along the Coronach axis was inhibited by the structural barrier of rigid salt substrate (stippled) of the western Roncott margin.

the central Rocky Mountains<sup>7-8</sup>, have been created by crustal downwarping reinforced by sediment loading. By contrast, solution subsidence as the cause of the Late Cretaceous to Lower Tertiary Wood Mountain-Willow Bunch delta complex suggests that loading is of minor importance. The crustal movement along the postulated geosuture was primarily lateral with minimal vertical component. Such movement does not preclude the development of vertical fracture zones into the Phanerozoic, including the Devonian salt beds to promote channelisation of sufficient fluids for regional dissolution.

The initiation of thick seams in the coal measures on the northern limb of the Williston Basin is transgressive southeastward towards the depocentre in northwestern North Dakota (Fig. 4). The thick seams of the Cypress Basin are at the base of the Tertiary (Ravenscrag Formation); the Ferris and superjacent Anxiety Butte seams, each developed to between 4 and 8 m thick. This interval is approximately isochronous with the relatively thinned Landscape seams, tens of metres higher in the stratigraphic section of the Coronach Trough, 200 km to the east. The Willow Bunch Basin subsidence did not diminish, to a rate permitting thick peat accumulation until the onset of the Hart seam 100 m higher in the section (Fig. 4). Similarly,

these conditions were not developed in the Estevan Basin, another 200 km to the east, until an additional 100 m of section was deposited above thinned and discontinuous equivalents to the Hart seam. The Boundary seam, the lowest of the thick seams in the Estevan Basin coal measures is isochronous on the basis of palynology with the main thick seam of the stratigraphically high Willow Bunch group across the Willow Bunch Basin (Fig. 4).

The onset of subsidence rates favourable for accumulation and preservation of thick peat sections is interpreted as a linear transgression up section as distal limb sections detach from the relatively rapid but diminishing subsidence of the cratonic basin. This is contemporaneous with the transition up section from subsidence dominated by salt solution to sufficiently diminished cratonic subsidence favourable for accumulation of thick peat sections in stagnant basins.

This work was supported by the Saskatchewan Department of Mineral Resources and the Geological Survey of Canada, 1971-77, and is based on a regional exploration programme involving the drilling of several thousand boreholes. I thank J. A. Irvine of the Institute of Sedimentary and Petroleum Geology (Calgary), and S. H. Whitaker of the Saskatchewan Research

## Primitive lead in an Australian Zn–Pb–Ba deposit

RADIOACTIVE decay of  $^{238}\text{U}$ ,  $^{235}\text{U}$  and  $^{232}\text{Th}$  yields  $^{206}\text{Pb}$ ,  $^{207}\text{Pb}$ , and  $^{208}\text{Pb}$ , respectively, as daughter products. This radiogenic lead is continually added to common lead in the source environments of ore deposits and the lead isotopic ratios of the resulting mixture are consequently time dependent. Because the relative proportions of these lead isotopes are fixed when the lead, common and radiogenic together, is separated from the parental uranium and thorium and incorporated into a lead deposit, determination of the isotope ratios provides evidence regarding the age of the lead ore and thus indirectly of the rock in which the ore is contained. Generally speaking, the older the ore the less radiogenic will be its lead. We report here analyses of extremely primitive lead from a small lead-bearing deposit in Western Australia.

The Big Stubby Zn–Pb–Ba deposits, located 5 km south of Marble Bar in the Pilbara Goldfield of Western Australia, have recently been described by Reynolds *et al.*<sup>4</sup> and their similarities to the Kuroko deposits have been discussed by Brook<sup>1</sup>. The conformable sulphide–sulphate deposits occur in an Archean volcanic sequence consisting of rhyolite breccias, rhyolite, and intermediate volcanics. Sphalerite and galena, dispersed within a barite gangue, are associated with a chert layer overlying a number of small rhyolite domes. The entire volcanic belt is intruded by granitic rocks dated at  $3.125 \pm 366$  Myr (ref. 3).

Five individual sulphide lenses are known at Big Stubby but only one, the 'A' Lens, has been systematically drilled where the best intersection is 4.27 m of 0.34% Cu, 4.5% Pb, 25.0% Zn, 1.071 g Ag per tonne and 15% Ba. Four intersections have been made in the 'A' Lens over a length of 500 m and the average grade is 0.26% Cu, 4.6% Pb, 16.5% Zn, 533 g Ag per tonne and 17% Ba.

It should be noted that the largest known barite deposits in Western Australia occur only 40 km WNW of Big Stubby and

**Table 2** Average isotopic compositions of lead from Old Star, Letaba and Big Stubby

Deposit	$^{206}\text{Pb}/^{204}\text{Pb}$	$^{207}\text{Pb}/^{204}\text{Pb}$	$^{208}\text{Pb}/^{204}\text{Pb}$	Ref.
Old Star	12.214	13.851	32.16	5
Letaba	12.679	14.089	32.51	5
Big Stubby	11.95	13.72	31.94	This work

have also been described as conformable deposits associated with sedimentary chert layers in an Archean volcanic sequence<sup>2</sup>.

Lead isotope analysis of three galena samples from Big Stubby are shown in Table 1. A significant feature of the Big Stubby lead is that it is the least radiogenic 'ore lead' reported to date, although feldspar from the Amitsoq gneiss of West Greenland contains lead which is even less radiogenic<sup>7</sup>. It is considerably more primitive than lead in galena from carbonate veins in the Old Star gold mine, South Africa, previously considered to contain the least radiogenic lead<sup>5</sup>. The same authors report that lead from Letaba, a subeconomic strata-bound massive pyritic deposit, although more radiogenic than that in the Old Star vein, is the least radiogenic found in a conformable deposit. It now seems that Big Stubby contains lead more primitive than either of these. Furthermore, an average of the Big Stubby data yields a model lead age of about 3,500 Myr according to the Stacey–Kramers model<sup>6</sup>.

For comparison, average isotopic compositions of lead from Old Star, Letaba and Big Stubby are presented in Table 2. Further lead and sulphur isotopic analyses of samples from this ancient segment of the earth's lithosphere are underway.

## East Anatolian earthquake of 24 November 1976

A DESTRUCTIVE earthquake occurred north of Van in East Anatolia on 24 November 1976 at 12:22:18.3 GMT (USGS epicentre: 39.10°N and 44.02°E; average magnitude:  $M_s = 7.3$ ). The earthquake did extensive damage, destroyed more than 80% of the dwellings in a 2,000 km<sup>2</sup> area and caused more than 4,000 deaths. In this area of complicated geology<sup>1–3</sup>, this was the only known large earthquake in the last century according to seismicity catalogues<sup>4–5</sup> and the recollection of villagers. The fault trace and the displacement were clearly visible and could be mapped for the total length of the fault. Furthermore, any precursory phenomena that might have preceded the earthquake as perceived by the local residents along the whole fault could be investigated. We summarise here the results of extensive field investigations carried out during the first 10 days immediately following the earthquake, and again in July 1977.

The location of the earthquake relative to major faults and earthquake epicentres is shown in Fig. 1. The earthquake is to the

Analyses were performed by Teledyne Isotopes, Inc., under the direction of L. Casabona. The data are corrected to absolute values on the basis of measured and absolute values for standard lead SRM 981<sup>8</sup>. The approximate 95% confidence level, based on the analysis of 20 duplicate samples, is 0.76%.

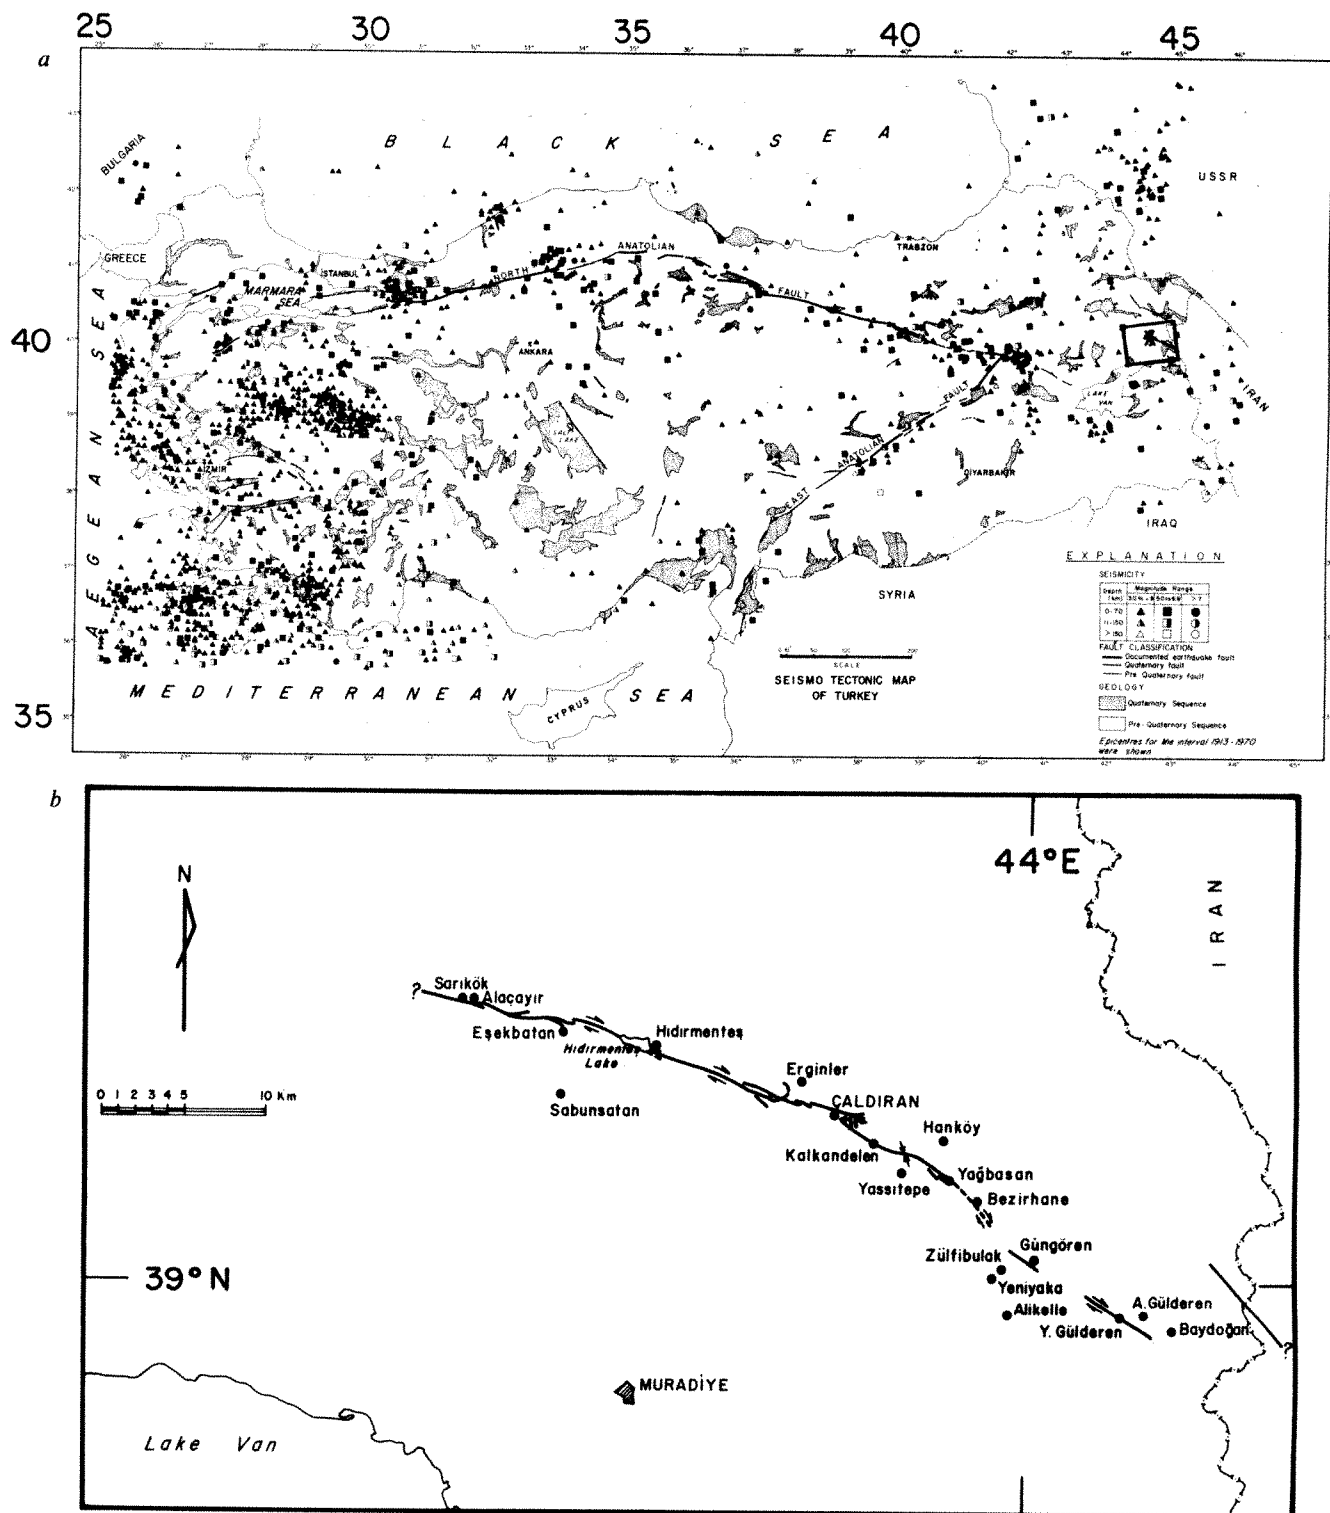

Fig. 1 *a*, Location of the earthquake within the seismotectonic setting of Turkey (inside the box), and *b*, detailed map of the observed fault trace.

east of the junction of the North Anatolian and East Anatolian Faults. The observed fault trace is to the north of a possible southeastern extension of the N. Anatolian fault trace through Lake Van. The connection of this earthquake fault with those in Iran is not clear, although there are a number of right-handed, strike-slip faults in Iran (branches of the North Tabriz fault) extending toward the Turkish border<sup>6</sup>. There are young volcanoes in the area and Tendurek, only 20 km north of the epicentre, has been active in the quaternary period. A more detailed description of the geology and tectonics of the region is given by Arpat *et al.*<sup>7</sup>.

The fault trace was clearly visible for about 50 km (Figs 1*b*, 2). The motion was almost purely right-lateral, strike-slip. The surface trace has a strike of about N 70°W in the central and western side and it bends somewhat east of Caldiran and continues along an azimuth of about 135°. The surface break is more prominent in the central and western sections, and has some *en-echelon* jumps in the east. The fault disappears abruptly under mountains in the west. At the eastern end the disappearance is gradual. The fault trace splinters and disappears toward the Iranian border. The observed horizontal displacements are more than 3 m (330–350 cm) in the west, about 250 cm in the central

regions and less to the east. The dip is nearly  $90^\circ$ . There are vertical displacements with inconsistent direction, generally about 50 cm, observed locally in several areas. The fault plane solution gives a right-handed, strike-slip source mechanism. The photographs in Fig. 2 show the fault trace and clearly document the right-handed motion. From the distribution of displacements, it seems that faulting may have started close to the west end and propagated to the east. The reported duration of severe shaking in Van was about 17 s, consistent with a fault length of about 50–60 km.

Seismic moment and stress drop can be calculated from the field observations. Taking the fault length  $L = 55$  km, assuming fault width  $W = 1/3 L$  and the average observed displacement  $D = 250$  cm, and rigidity  $\mu = 4 \times 10^{11}$  dyn cm $^{-2}$ , the seismic moment is  $\bar{M} = 1.0 \times 10^{27}$  dyn cm. The stress drop calculated using a strike-slip model is  $\Delta\sigma = 35$  bar. Comparing this value with those of other earthquakes, we find that the stress drop falls within the general range of those inter-plate earthquakes<sup>8</sup>. The observed displacements and calculated stress drop, however, are high as compared with some other strike-slip earthquakes. The relatively young age of the fault and the recent basalt flows across which the fault cuts may be responsible for this deviation.

There were no instruments in the area except for a seismoscope in Van, about 90 km to the south-west of the epicentre. A county centre, however, (Caldiran) and about 20 villages were located directly on the fault trace. The reports from these and other affected villagers were gathered (mostly through personal interviews) regarding the pre- and post-earthquake phenomena. The earthquake occurred at 2:22 p.m. local time. Most villagers raise livestock. About half the people were outdoors tending their herds. Because of high regional elevations, the weather was already cold and in the western end, the ground was covered with snow.

There were no foreshocks felt along the fault zone before the main shock on 24 November 1976. In two villages along the western half of the fault trace, where displacements were highest, noises resembling thunder were heard several times during the week preceding the quake. These could have been due to small foreshocks, even though the shaking was not felt. In the village of Hidirmen, directly on the fault trace and where it cuts the lake, there were reports of noises coming from the lake (foreshocks, gas release, microfracturing?) during the same period. There was no observable change in water level before the earthquake.

There was one reported case of change in ground water activity before the earthquake: in the village of Yukarigölder, near the eastern end of the fault trace, discharge from a spring increased. Also associated with this increase was seepage of oil that covered the water surface. There are cases of oil seepage in this general area.

After the earthquake, major changes in ground water conditions were noticed both near the fault trace and on the southern side. Some springs became muddy and stayed so for days. A few springs dried on the north side of the fault and a well went dry in the south. At Tuzla, 50 km south of the fault trace, discharge from the salt spring increased by a factor of 20 immediately after the earthquake and it was three times normal a week later. The north shore of Lake Van was uplifted relative to the south shore by about 16 cm. The southward tilting of the lake was most likely co-seismic, but a deformation before the earthquake cannot be ruled out.

Behaviour of domestic and farm animals before the earthquake was investigated extensively by interviewing many villagers and shepherds. In this primarily ranching area, there are cattle, sheep, goats, horses and dogs. The animals are housed in barns adjacent to the houses, although at the time of the earthquake most were outdoors. We inquired in widely scattered villages along the fault zone. There were no confirmed observations of unusual behaviour of farm animals, outdoors or indoors, before the earthquake. There was one report of animal restlessness in a village on the western end of the fault that reportedly lasted for months before and after the quake. This was not observed at neighbouring villages. The barking and howling

**Fig. 2** Photographs of the fault trace observed immediately after the earthquake. *a*, The fault trace photographed from a distance. *b*, The right-handed displacement is clearly visible by the 250-cm offset of a ditch.

dogs were widely reported in a number of villages located on the west, central and eastern parts of the fault. The reported timing, however, of these events varied from a few minutes to a few hours before the earthquake.

Since there had been no major earthquakes in this region for a few generations, the villagers in general had no ideas or preconceptions about earthquakes. We believe that the reports we received were unbiased. There was no wide-scale abnormal behaviour of farm animals before the earthquake, except possibly for the behaviour of dogs. Physical precursors were definitely observed before the earthquake.

We thank the MTA Institute and its Van regional office for support which made the field studies possible. Dr A. Boray contributed the regional map in Fig. 1. This research was supported by the Advanced Research Projects Agency, monitored by the Air Force Office of Scientific Research (contract F44620-75-C-0064) and by NATO (Science Grant No. 1162).

## Timing of continental growth and emergence

HARGRAVES<sup>1</sup> has proposed that the separation of the primordial shells of the earth into continents and oceans began only about 3,700 Myr ago and continued through most of Precambrian time, with the result that the bulk of the continents as we know them today did not emerge from the sea until 1,400–1,000 Myr ago. Here I review geological and geochemical data that indicate that the growth and emergence of the bulk of the present-day continents took place in or by  $2,500 \pm 200$  Myr ago.

There are many estimates of the thickness that the continents had reached by the late Archaean. First, studies of mineral assemblages and chemistry correlated with experimental data on 3,000 Myr high-grade rocks from Greenland, Scotland, Africa and India suggest they formed at depths of 30–50 km (refs 2–5) and, because the Moho is 35–40 km beneath them, the Archaean crust in these regions was probably at least of the order of 65–80 km thick<sup>3,8</sup> (this discounts the unattractive alternative of subsequent sialic underplating to make up the difference), comparable to the continental crust today in the Andes<sup>6</sup>. These calculations are not surprising if the major period of crustal growth took place in the late Archaean by Cordilleran plate margin activity<sup>5,7</sup>. Extensive thickening of the crust in the late Archaean could have been effected by a combination of thrust-nappe stacking and magma addition<sup>8–10</sup>. Second, for greenstone belts mostly in North America, Condie<sup>3</sup> calculated crustal thicknesses primarily in the range of 20–30 km from Rb–Sr data, and of 20 km from K<sub>2</sub>O–SiO<sub>2</sub> data. Potash and Rb–Sr indices of granitic rocks suggest crustal thicknesses equal to or more than 30 km at the time of granite emplacement late in the evolution of the greenstone belts. Consideration of the spacing between volcanic centres in the Abitibi belt in relation to the known dependence of modern volcano spacings on crustal thickness gives an Archaean crustal thickness of 35–45 km (ref. 11). In comparison with the thickness estimates from the high-grade regions these values are consistent with formation of greenstone belts in some primitive form of marginal basin environment<sup>12,13</sup>. In spite of various problems connected with the interpretation of geobarometry, the above estimates suggest that the major stage of crustal fractionation was completed by the end of the Archaean.

There are many reasons for regarding the Archaean–Proterozoic time boundary (some  $2,500 \pm 200$  Myr ago) as the most important turning point in the evolution of the continents<sup>14–16</sup>; it represents the changeover from a permobile regime to a platform-geosynclinal style of tectonics that begins to show strong similarities with that of modern times. Indications of the new-found stability of the early Proterozoic continents include the intrusion of transcontinental basic dyke swarms, and the first appearance of alkaline complexes, kimberlites, carbonatites and aulacogens that extend from continental margins into the interior of stable plates. But the best evidence of the widespread emergence of stable cratons in the early Proterozoic is the appearance of miogeoclinal and geosynclines with the first recognisable continental margin sequences.

Many Archaean cratons are bordered, or partly underlain, by early Proterozoic sedimentary basins—an indication that the cratons were positive emergent areas bordered by shorelines in the early Proterozoic. One of the best-documented studies of craton-basin relations is by Hunter<sup>17</sup>, who has followed the development of basins in the Kaapvaal craton of southern Africa from about 3,300 to 1,850 Myr ago. He showed that the rates

of vertical movement of the basins decreased with time, which is consistent with the observed increase in volume of finer clastics and non-clastics in successively younger basins, and also estimated the percentage increase in inundation of the Kaapvaal craton by shallow Proterozoic seas, which took place by episodic regressions and transgressions. The data indicate that the craton was an emergent area more in the Archaean than the Proterozoic, the peak of continental emergence being reached between 3,350 and 3,000 Myr ago. Exposed mountains were gradually eroded during the Proterozoic, increasing the availability of sialic clastic debris and enabling increasing transgressions by epicontinental seas. This picture is at variance with the proposals that the Archaean continents were submerged beneath a globe-encircling sea, that the height of mountains increased during the Proterozoic, and that continental emergence did not take place on a substantial scale until after 1,400 Myr ago in the late Proterozoic<sup>1</sup>.

**Table 1** Some early Proterozoic geosynclines and basins in the North American Shield

Succession	Abbreviation on Fig. 1	Thickness (km)	Ref.
Huronian Supergroup	H	~12.0	19
Animikie Group	A	7.5	19
Coronation Geosyncline	C	10.7	20
Circum-Ungava Geosyncline	CU	> 15.0	21
Ramah Group, Labrador	R	1.7	22
Baffin Geosyncline	B	?	23
Chibougamau Group	CB	1.1	24
Wollaston Lake Fold Belt	W	?	21
Thompson Fold Belt	T	?	21
Hurwitz Group (Kaminak Subprovince)	K	4.0	21
Medicine Bow Mountains, Wyoming	M	8.0	24

Hunter's data are echoed in a more general way by Watson's<sup>18</sup> review of vertical movements during the Proterozoic. She concludes that erosion of Archaean cratons down to the present level of exposure was completed in periods of no more than 300 or 400 Myr after their stabilisation, and that the cratons typically underwent very limited vertical movements after about 2,000 Myr ago.

The North American shield contains a large number of early Proterozoic geosynclines and basins (in the Aphebian age range, 2,560–1,800 Myr), some of which are shown in Table 1 (see also Fig. 1).

These Aphebian successions, many of which are unconformable, overlie or border Archaean cratons for a minimum total length of 8,000 km (Fig. 1). Besides iron formations and dolomites the sediments consist predominantly of clastic conglomerates, quartzites, siltstones, shales and sandstones. It is evident that over the whole shield Archaean mountains were being eroded to provide great thicknesses of terrigenous clastic debris in the early Proterozoic<sup>14,25</sup>. The Huronian is a miogeoclinal sequence containing craton-derived sediments on the south side of the Superior Province<sup>19</sup>. The Coronation Geosyncline has a stratigraphy and structure that so faithfully mirrors that of modern Cordilleran successions that it is highly likely that modern-style plate tectonics began by the early Proterozoic<sup>20</sup>. The Circum-Ungava Geosyncline probably formed in a narrow ocean or rift that was closed by continent–continent collision<sup>26,27</sup>. The North American successions are no doubt only remnants that were once more extensive, but, nevertheless, they are sufficient indication that the bulk of the Archaean shield was undergoing uplift and emergence in the early Proterozoic.

Fig. 1 Early Proterozoic geosynclines in the North American Shield. For abbreviations see Table 1. Compiled from refs 21, 24, 25.

There are well-known comparable early Proterozoic successions on all other continents, which abound in clastics and which indicate that Archaean cratons the world over were being highly eroded and many were at or near sea level by the early Proterozoic.

Rb-Sr and Pb-U isotope systematics yield information on the timing of fractionation of continental crust. For example, the growth of the strontium isotope ratio with time and the variable intercepts with the primary growth curve in the lead isotope system may be used to distinguish juvenile addition or accretion of mantle-derived material to the continental crust from rejuvenation or reworking of continental basement<sup>28,29</sup>. Table 2 shows estimates of the percentages of present-day continental crust formed by the late Archaean.

These values agree with estimates, based on areas of rock distribution, that at least 50% of North America<sup>34</sup> and Africa<sup>35</sup> were in existence by 2,500 Myr ago. If 50% of the volume of the present continental crust was formed by about 2,500 Myr ago it is possible that the continents have been growing more or less linearly during geological history<sup>33</sup>. There is increasing evidence, however, that the growth of the present-day continents, both in terms of surface area and thickness, was probably almost complete by 2,500 Myr ago (see below).

The model strontium isotope curve for the evolution of seawater shows a marked increase about 2,600 Myr ago, which is consistent with a major stage of crustal fractionation at that time<sup>33</sup>.

The factors of continental area and thickness, and the evidence of early (Archaean) crustal thickening and of early (late Archaean) emergence of continents above sea level, are interrelated. This interdependence is well illustrated by the conclusions of Wise<sup>36</sup> of freeboard (elevation of continents with respect to sea level) as a function of time: (1) the continents have had at least

90% of their present thickness for a minimum of 2,500 Myr. (2) There has been isostatic balance (constant freeboard) between oceanic and continental crusts throughout the Proterozoic and Phanerozoic, that is continental and oceanic volumes and areas have not changed significantly in this time span.

This picture is supported in particular by Watson's<sup>19</sup> conclusion about the lack of vertical movement of Archaean cratons for the last 2,000 Myr, and by the fact that the present thickness of continental crust in belts reworked at different times throughout the last 2,500 Myr is constant (38–40 km range) and independent of age<sup>37</sup>.

Isostatic modelling<sup>1</sup> shows that a 30-km thick crust can support ideally mountains that rise 2 km above sea level. Because there is widespread evidence that the continental crust had reached such a thickness by the late Archaean, it can be supposed that there were 2 km high mountains at that time in greenstone belt country—a likely result of vertical movement at a rate of 0.27 km Myr (ref. 17)—and even higher mountains above granulite-gneiss belts. Erosion of such elevated continents may account for the high proportion of immature sediments (arkoses and greywackes) in late Archaean greenstone belt sequences, the recycling of which during later geological time contributed to more mature detrital sediments (shales, sandstones and quartzites)<sup>38,39</sup>.

In Phanerozoic time continental fragmentation was accompanied by transgressions, and continental assembly by regressions<sup>40</sup>; it has long been known that the periods immediately following the formation of the Caledonian, Hercynian and Alpine fold belts were characterised by regressions<sup>40</sup>. In the mid-late Archaean the most intense period of 'orogenesis' and continental growth in earth history most likely resulted in the assembly of a large number of small plates (because of a greater ridge and subduction zone length) into more extensive, thick and stable plates by the early Proterozoic<sup>15,16</sup>. Because regression follows orogeny and accompanies continental assembly, the Archaean-Proterozoic boundary probably marks a period of profound regression followed, in the early Proterozoic, by widespread transgression that led to the formation of thick carbonate banks (for example, Coronation and Mount Isa Geosynclines) and miogeoclines (for example, Huronian Supergroup and the Western Labrador Trough).

## Alcohol retards visual recovery from glare by hampering target acquisition

ADAMS and Brown<sup>1</sup> showed that relatively small doses of alcohol produced “large, significant, dose-related increases in the time required to recover foveal contrast sensitivity following bright light exposure”. As this effect of alcohol may be directly related to industrial and to car driving safety<sup>2</sup>, we set out to ascertain its precise origin. Adams and Brown concluded tentatively that the alcohol exerted its effect at the retinal level. The experiments presented here, however, implicate non-retinal mechanisms, as alcohol delays recovery from glare only when observers have difficulty localising or fixating the test stimulus.

The first part of our study was a replication of the Adams and Brown experiment. Our subjects were four male college students with normal (6/6) or corrected-to-normal visual acuity. On separate days subjects ingested either alcohol (1.0 ml per kg body weight) or placebo. The two treatments were given in random order. The alcohol dose was 95% ethanol diluted 2:1 with fruit drink so that the total volume (ml) was three times the subject's weight (kg). The placebo was an equivalent volume of fruit drink alone. The drink was consumed in 20 min from a paper cup containing two ice cubes. In addition, 2 drops each of ethanol and eucalyptus oil were placed on the lid of the cup to minimise olfactory cues to the presence of alcohol<sup>1</sup>.

Details of stimulus presentation are given in Fig. 1. Subjects practiced the detection task to achieve stable performance at the beginning of each experimental session; they then were tested before drinking, and 30, 75, 150, 240, and 330 min after drinking. At each of these times, three sets of measurements were taken with 5 min allowed between sets to allow complete recovery from the adapting luminance level. The session always started in the early afternoon, and subjects were instructed to eat lunch beforehand.

As expected, alcohol produced large, significant increases in the time required to recover foveal contrast sensitivity. In particular, as Fig. 1 shows, the difference between recovery times with and without alcohol is maximum at the sampling time 75 min after ingestion and declines thereafter, and is most pronounced at low target contrasts. Analysis of variance (ANOVA) indicates that the depicted interaction between dose, time, and contrast level is statistically significant ( $P < 0.001$ , d.f. = 20, 60).

A simple but trivial explanation of the results of Adams and Brown and of our replication would be that following alcohol ingestion observers become more cautious about reporting the visibility of the test target, thereby spuriously increasing recovery times<sup>3,4</sup>. We decided therefore to use a methodology<sup>5</sup> which could discriminate alcohol-induced changes in sensitivity from changes in criterion (that is, willingness to report).

Using the same apparatus as before but without a glare source, we tested seven male college students. On half of the 2-s trials the small flickering test spot actually was presented; on the remaining trials no spot was presented. The subject's task was to respond either ‘yes’ (a test spot had been presented) or ‘no’. With each subject, 500 trials were run at various spot

**Fig. 1** *a*, The stimulus configuration of the  $8.6 \times 10^4$  cd m<sup>-2</sup> glare field on the left and the test field on the right. The 10 min arc test spot was located at the centre of the test field reference markers on a background of luminance 24.8 cd m<sup>-2</sup>. In the actual experiment, the glare field was located directly above the test field, which was at eye level. At the beginning of each measurement session, the subject fixated with his left eye the centre of the circular adapting (glare) field. The right eye was covered with a patch, and fixation was aided by four thin diagonally-orientated reference lines. Immediately after a 60-s exposure to the high intensity glare source, and with the eye-patch still in place, the subject looked directly below (straight ahead) and fixated the centre of the test field on which a test spot was presented intermittently (125-ms flashes at 4 Hz). The contrast of the test spot was under the experimenter's control. When the subject indicated orally that he saw the spot at the highest contrast level, the experimenter rotated a filter wheel one notch, reducing the target contrast a further step below the subject's threshold. When the subject's contrast sensitivity had recovered enough to restore the test spot to detectability, the spot contrast was reduced again. The time taken to recover to each of five predetermined contrast levels (0.72, 0.48, 0.33, 0.27, and 0.24) was obtained. These levels were chosen to give approximately equal intervals between each recovery point. *b*, Interaction of alcohol, contrast, and time for the first experiment. Each point is the mean difference (s) between recovery time with alcohol and recovery time with the placebo. Data from four subjects.

contrasts. Subjects were tested either following ingestion of alcohol (dose identical to that used before) or following ingestion of the placebo. Intermittent tests were carried out 30–140 min after ingestion, when glare recovery was most seriously retarded in our original experiment. The conditional probabilities of ‘yes’ responses in the presence of a test spot and ‘yes’ responses in the absence of a test spot were used to estimate<sup>5</sup> the observer's response criterion ( $\beta$ ). Analysis of variance indicated no significant alcohol-induced changes in  $\beta$  ( $P > 0.50$ ).

With response bias eliminated as an explanation, we sought to identify the source of the alcohol-induced delay in glare recovery times more precisely. Four new subjects participated in an experiment identical in every respect to our first, except that three sets of eye movement measurements (before, during, and after exposure to the glare) were taken every 15 min for 135 min following the 20-min drinking period. Standard electrooculographic<sup>6</sup> (EOG) methods produced records of eye position as a function of time. The resolution of our recordings was approximately one degree of visual angle.

With or without alcohol, very little eye movement occurred either before or during exposure to the glare source. But immediately after the 60 s of high intensity glare, there were many eye movements as if subjects ‘hunted’ for the flashing spot within the test field; after alcohol ingestion the eye movements were larger and more frequent. These eye movement patterns suggested that alcohol might combine with glare to prolong recovery time by impeding the subject's attempts to localise and fixate the target. Localisation would be hampered if alcohol ingestion were to disturb the subject's memory of precisely where the target would appear. Steady fixation would be hampered if alcohol were to impair control of the extraocular muscles<sup>7</sup>. Irregular visual fixation could produce enough

uncertainty about the target's spatial location to reduce its detectability<sup>8</sup>.

Three of the four subjects who participated in our original study were available for two additional experiments. In the first, the test spot locus was circumscribed by a small, dark circle, 12.5-arc min diameter. The circle was of high contrast, and clearly visible immediately after glare exposure even though the flashing test spot within was not. As a result, the subject would not have to remember where the target might appear thereby aiding target localisation. Details of the experimental design and procedure were as in the original experiment, except that the test spot luminance was three times that of the spot in the original experiment. In a second experiment, the test spot was enlarged (100-arc min diameter) to fill the entire area between the arrow reference marks (Fig. 1). Consequently, no matter where between the arrows the subject looked, his fixation would fall on some part of the flashing test spot. Enlarging the area of the test spot reduced its maximum luminance; to compensate, we reduced the background luminance to 0.89 cd m<sup>-2</sup>. In both these experiments, as before, glare recovery was measured with spots whose contrasts covered a range of 0.5 log units; a single set of five measurements was made before, and 30, 90, 150 and 210 min after drink ingestion.

As shown by Fig. 2, the effect of alcohol on recovery from glare was greatly reduced when either the small test spot was circumscribed by a clearly defined circle or the test spot was enlarged. With the enlarged test spot, no effects involving alcohol were statistically significant (ANOVA, all  $P > 0.5$ ). This is what would be expected if the alcohol-induced retardation of glare recovery in our original experiment had been partly caused by an unsteadiness of fixation which the enlarged test spot rendered unimportant. The contrast independent elevation shown in Fig. 2 is not statistically significant ( $P > 0.80$ ) and is due to greatly increased recovery times for just one subject. With the small, circumscribed test spot, one effect involving alcohol (the interaction of alcohol and contrast) was significant ( $P < 0.03$ , d.f. = 4, 8), due mainly to the increased recovery time at the lowest contrast level. This reduced effect of alcohol would be expected if in our original experiment alcohol had made subjects unsure about the location of the target and if the easily seen, high-contrast circle in the present experiment had made them less unsure. The small residual effect of alcohol may reflect difficulty in maintaining precise fixation following alcohol consumption, a problem that would be less critical with the enlarged spot.

Our experiments confirm that ingestion of alcohol causes a

**Fig. 2** Mean difference (s) between recovery time with alcohol and recovery time with the placebo. Data are shown for all five contrast levels and for all three glare experiments. The data have been normalised in both this figure and in all analyses of variance to produce 47.52-s average recovery time for each subject (the average for the original experiment). Only the data from those subjects who participated in all three experiments are shown. Data shown were collected at those times following alcohol ingestion which should have produced the largest effect of alcohol: 75 min for the original experiment (●), 90 min for the large spot (□), and 90 min for the circumscribed spot (△).

loss of visual sensitivity following glare. But non-retinal processes are primarily responsible for the effect of alcohol on glare recovery. We emphasise that the non-retinal origin of this alcohol-induced visual disability does not lessen its potential for adversely affecting driving and related visual tasks. On the contrary, uncertainty about the location<sup>8</sup> of possible targets imposes an inescapable reduction of visual sensitivity of any driver; if alcohol either retards a driver's target acquisition<sup>9</sup> or causes him to mislocalise the target<sup>10</sup>, visibility necessarily will be reduced and his ability to respond to the target impaired. Moreover, we cannot rule out the possibility that in driving, the effect of alcohol that we studied can sum with other, previously identified perceptual consequences of alcohol ingestion<sup>11</sup>.

## Visual discrimination between small objects and large textured backgrounds

THE remarkable ability of certain higher order insect visual neurones to discriminate between movement of a small object or target and a large textured background has been clearly demonstrated by Palka<sup>1,2</sup> and O'Shea and Fraser-Rowell<sup>3</sup>. In addition, movement of a large textured background such as a windmill pattern is inhibitory to detection of motion of a small target by this neurone, known as the descending contralateral movement detector (DCMD). The response of this identifiable neurone to motion of small objects is inhibited by rotation of the windmill pattern over a specific range of high spatial frequencies of the pattern, but is augmented by low spatial frequencies in the pattern. For this neurone we have quantitatively determined the spatial frequency at which the effect of the windmill pattern becomes inhibitory.

The DCMD is a visual interneurone in the ventral nerve cord which is excitatory to motor neurones involved in jumping. It originates in the protocerebrum where it receives excitatory input through an electrical synapse from the LGMD (lobular giant movement detector) which has a dendritic field in the shape of a fan across the entire lobula. The LGMD receives at least two kinds of inhibitory inputs: lateral inhibition on neurones peripheral to the fan of dendrites, and inhibitory input proximal to the convergence of the fan of dendrites (post-convergence inhibition)<sup>3,4</sup>. The post-convergence inhibition samples activity across the entire visual field but is effective only for higher velocities<sup>3,4</sup> of patterns than used in these experiments.

Responses of the DCMD in *Schistocerca gregaria* were obtained by conventional methods<sup>2</sup>. The receptive field of the DCMD is approximately a hemisphere, and motion detection

does not depend on the direction of motion<sup>5,6</sup>. The region of greatest sensitivity lies along the equator posterior to the animal's transverse plane, and it is primarily this region which was tested in these experiments. Two visual stimuli were presented. One, an approximately 5° (in visual angle subtended at the cornea) light disk which is occluded by a moving edge, yields a large sustained train of spikes over the entire time

**Fig. 1** Sets of PST histograms demonstrating inhibition of small target response by radial grating pattern. This set of histograms is to be viewed in sequential groups of three traces. R refers to rotation of the radial grating pattern only, T refers to motion of the edge in the small disk only, and RT refers to simultaneous radial grating pattern rotation and edge motion. Radial gratings are of 90 black and white stripes of equal angular width (a), 40 stripes (b), 20 stripes (c) and 10 stripes (d). This figure shows, for 90, 40 and 20 stripes, that the excitatory response to the motion of the small target alone (traces T) precedes the inhibition due to the simultaneous radial grating rotation (traces RT). In the second trace from the top (a), marks inhibition occurring at the falloff of response to small target motion. Patterns and disk are adjacent along the equator with disk posterior, and are 9 inches from the cornea; the radial grating subtends 37° visual angle and the disk 5.6°. Time of initiation of motion is shown by small vertical bar near centre, below each trace, so that spontaneous activity is seen to the left; motion terminates at end of record. Each trace represents 17 trials, and the T and RT are interleaved with 30 s interstimulus interval (ISI). The R are a separate run with 30 s ISI. Experiment of 21 February 1976, light surround (see Fig. 2); order of T/RT was 90, 20, 10, 40 stripes; order of R was 10, 40, 20, 90; time bar 100 ms; vertical scale 59 spikes per s; sustained baseline is 0 spikes per s.

course of motion of the edge. The other, a large circular radial grating pattern (windmill pattern) of an adjustable number of alternating black and white stripes of equal width which is rotated about its centre, yields a burst of spikes only on initiation of rotation regardless of velocity.

In Fig. 1 the post-stimulus time (PST) histograms are shown for a typical experiment to illustrate the nature of the inhibition in time. For these experiments the clearest distinction between small objects and large backgrounds can be made in the spatial frequency domain. The spatial frequency spectrum of an intensity pattern is given by the Fourier transform of that pattern. This calculation shows that the magnitude of the spatial frequency spectrum of the radial grating pattern has a minimum sensible spatial frequency of approximately  $0.85F$  and peak spectrum spatial frequency of  $1.09F$ , where  $F$  is the single number spatial frequency geometrically calculated as  $1/L$ ,  $L$  being the angular distance subtended by one stripe cycle at the outermost edge of the pattern. In Fig. 2 this geometric value of  $F$  has been used, which represents the 25% of peak spectrum point. (Note: in ref. 7, page 336, the value  $0.85F$  erroneously reads  $1.3F$ , and  $1.09F$  erroneously reads  $1.64F$ .)

The spatial frequency components of the moving edge in the small disk are predominantly at low spatial frequencies, which is complementary to the situation for the radial grating pattern.

In Fig. 2 the inhibition  $I$  of the response to the small target caused by the radial grating pattern is plotted as a function of  $F$ , the nominal minimum spatial frequency of the radial grating. Since the curve is positive for  $F$  greater than 0.05 cycles per degree the radial grating is inhibitory when all of its spatial frequency components lie above 0.05 cycles per degree. When any of its components lie below 0.05 cycles per degree the radial grating becomes excitatory to the response to the small target, as the curve there is negative. The peak of the curve lies at about 0.2 cycles per degree which is thus approximately the spatial frequency of maximum inhibition. The curve falls to zero at 1.0 cycles per degree because that is the maximum resolvable spatial frequency for this animal<sup>7</sup>. Thus low spatial frequencies are excitatory and high spatial frequencies are inhibitory to the response to low spatial frequencies, as long as the high spatial frequencies are resolved. In Fig. 2 a further difference in the DCMD responses elicited by high and low spatial frequency stimuli is greater variability to low excitatory spatial frequencies than to high ones. At lower spatial frequencies fewer ommatidia are stimulated by a moving pattern so that higher integrative units have either fewer inputs to average, or are more susceptible to their inherent noise.

A peaked inhibition curve like that of Fig. 2 can be obtained with radial grating pattern diameters down to a minimum of 30° (visual angle). Inhibition could occasionally be found at 0.2 cycles per degree for radial grating pattern diameters down to a minimum of 10°. The conclusion is that the radial grating patterns become inhibitory backgrounds at the optimal inhibitory spatial frequency if their diameter exceeds 10°, but for inhibition to occur over a measurable range of spatial frequency their diameter must exceed 30°. The inhibition is not uniformly dependent on the distance between the radial grating pattern and the small target. The inhibition is also not dependent on grating rotation velocity below about 300° (pattern plane angle) per s.

A model for the observation that stimuli with predominantly high spatial frequency components are inhibitory to those with low ones can be based on optic lobe electrophysiology any neuroanatomy of locust<sup>8,9</sup> and dipterans<sup>10,11</sup>. Arnett<sup>10</sup> had shown that movement of a small contrasting pattern can be detected by first order interneurons (monopolar cells), and lateral inhibition has been demonstrated in locust optic lobe by Horridge *et al.*<sup>8</sup>, and O'Shea and Fraser-Rowell<sup>3,4</sup>. A detector of high spatial frequencies can be derived by spatial summation over the entire visual field of monopolar cell outputs, and a detector of primarily low spatial frequencies can be derived by spatial summation over the entire field of another set of monopolar cells having lateral inhibitory connections among

**Fig. 2** Inhibition ( $I$ ) of response to motion in small disk plotted as a function of the lower limit,  $F$  (cycles per degree visual angle subtended at cornea), of spatial frequency content of the radial grating pattern. Inhibition  $I$  is defined as  $(NE - NI)/NE$ , where  $NE$  is the number of spikes in the DCMD in response to motion in small disk alone, and  $NI$  is the number of spikes in response to simultaneous motion in disk and rotation of the radial grating pattern. When the number of spikes in response to simultaneous motion  $NI$  is greater than  $NE$ , inhibition  $I$  becomes negative and is, in fact, excitation. In all experiments, these two kinds of trials are interleaved to increase stability of the measurement. ●, Average of means of continuous series of 14 experiments 12 December 1975–14 February 1976 in completely dark surround. ○, Average of means of continuous series of three experiments in light surround, 17–21 February 1976. Light continuous dotted line, negative of response to rotation only of radial gratings from data of acuity studies of 1972<sup>2</sup> to show acuity limits inhibition at high frequencies. △, Data of one experiment (21 February 1976) in light surround; bars indicate  $\pm$  the sum of standard error of  $NE$  and  $NI$ ; each point is the mean of 34 or 68 trials with 30-s ISI and interleaved presentation of disk motion trials with simultaneous disk motion and radial grating rotation. ■, Average of active controls on dark surround experiments. □, Average of active controls on light surround experiments. ▽, Active control on single light surround experiment. (An active control is rotation of the unilluminated radial grating with disk motion.) Stimulus parameters: luminance of a brighter bar of radial grating,  $1,200 \text{ lm m}^{-2}$ ; dark bar,  $\sim 0 \text{ lm m}^{-2}$ ; small disk has luminance equivalent to bright bar of radial grating; light surround luminance approximately  $1.5 \log_{10}$  units below that of bright bar; when the disk is occluded in light surround, the occluded portion has the luminance of the surround, but the excitatory response is approximately the same as in dark surround. The radial grating tangential velocity is  $11^\circ$  (visual angle) per s for most runs of this figure, or  $36^\circ$  per s in pattern plane angle. The velocity of translation of the occluding edge is  $12^\circ$  (visual angle) per s, and the light disk subtends  $5.6^\circ$  (visual angle); the radial grating subtends  $37^\circ$  (visual angle) for all but a few runs of this figure. In all experiments except as noted the disk and grating pattern are directly adjacent along the equator.

themselves. In the locust the latter summation would take place as excitatory synapses at or before the fan of LGMD dendrites in the lobula<sup>4</sup> via interneurons from the medulla, and the former summation as inhibitory synapses from the first set of monopolars on to these interneurons in the medulla. Since the LGMD drives the DCMD directly, this model gives for DCMD response two separate channels selectively responding to high and low spatial frequencies respectively, with an inhibitory cross-connection from the high frequency channel to the low frequency channel. Further tests of these ideas require probing of more peripheral units than the LGMD.

In vertebrate vision the reduction of retinal sensitivity during relative motion of retina and image is known as saccadic suppression. The suppressive or inhibitory effect on human vision (measured with a low spatial frequency test flash) produced by relative motion of gratings<sup>12,13</sup> is parallel to the above results for the locust DCMD. It is of interest that the locust visual system processes high and low spatial frequency image information in the same manner as do some perceptual

channels of the human visual system.

## Contribution of stored pre-anthesis assimilate to grain yield in wheat and barley

RESERVES of assimilate present in wheat and barley crops at flowering, and available for later translocation to the grains, could buffer grain yield against environmental stresses during grain filling. This so-called pre-anthesis assimilate contribution to grain yield can be expressed as a percentage of yield ( $P_1$ ). Archbold<sup>1</sup>, and later Thorne<sup>2</sup>, concluded that  $P_1$  was small, being no more than 20%. But only one result (12% for irrigated wheat at Cambridge<sup>3</sup>) refers to a crop in the field as distinct from plants in pots, and no studies considered the effect of stress during grain filling. Recently Gallagher *et al.*<sup>4,5</sup> reported substantial contributions:  $P_1$  averaged 43% over six crops of wheat and barley at Nottingham; this amounted to more than 300 g per m<sup>2</sup> of dry material in two crops and, in the severe drought of 1970, 39% of total dry matter present at anthesis. They assumed, with some supporting evidence from one barley crop<sup>6</sup>, that the pre-anthesis contribution was given by the decrease from anthesis to maturity in dry weight of non-grain parts of the crop. *In situ* labelling with <sup>14</sup>CO<sub>2</sub> of the whole crop canopy at frequent intervals before and after anthesis would seem to be the least equivocal way of estimating  $P_1$ . Using this method we have determined  $P_1$  in wheat and barley. It averaged only 12% (watered crops) and 22% (droughted crops), and did not agree with estimates for the same crops obtained by the method of Gallagher *et al.*<sup>4,5</sup>.

Wheat and barley were grown during 1974–75 at the Centro de Investigaciones Agrícolas del Noroeste (CIANO) near Ciudad Obregon in north-west Mexico. There was no rain and crops were either flood irrigated frequently (I) or only until 27th January, about 40 d before anthesis, creating a drought (D) regime. Weather and general experimental procedures were as described elsewhere<sup>7</sup>. Grain yields for regime I were high (Table 1). Significant differences between D and I in leaf water potential arose about 10 d before anthesis and then increased steadily. There were substantial reductions in yield in regime D, especially for the wheat cultivars, which were later in flowering (Table 1).

The canopy labelling with <sup>14</sup>CO<sub>2</sub> began on 20 February and was repeated on separate 1.08 m<sup>2</sup> portions of the crops every 7–14 d until near maturity. The proportion of total above ground <sup>14</sup>C at maturity found in the grain was slightly greater for any given date of labelling in regime D, but was remarkably consistent between cultivars and species (Fig. 1). The relationship of Fig. 1a agrees with results<sup>2,8,9</sup> obtained in non-crop conditions.

Combining the data of Fig. 1 with information on changes in above ground dry weight,  $P_1$  was estimated to be 12–13% under

frequent irrigation, rising to 27% for droughted wheat (Table 2). But in absolute terms (grain dry weight,  $GDW_1$  in  $g\ m^{-2}$ ), it was similar for regimes I and D. As a proportion of total dry weight at anthesis,  $GDW_1$  amounted to 8.5% (I) and 11.5% (D). Considering that  $GDW_1$  for barley included the husk, already present at anthesis and amounting to 8% (I) and 9% (D) of final grain weight, the true contribution of stored pre-anthesis assimilate was clearly lower for barley than for wheat.

The method used to estimate  $P_1$  in Table 2 assumes that any contribution of carbon from roots, or variation in the proportion of carbon to dry matter in the total crop compared with that in the grain, or fluctuations in crop growth rate within the two key periods, are of minor importance. On the other hand, neglect of the loss of tissue, formed before anthesis, and lost during the post-anthesis period could be important. Such losses seem to be substantial under irrigation, probably due to the saprophytic decay of lower early-formed, and hence unlabelled, leaves. A loss of  $100\ g\ m^{-2}$  would seem probable (R.A.F., unpublished) under the I regime, and correcting  $\Delta TDW_2$  ( $TDW$ , total dry weight) for this would increase  $GDW_2$  by  $75\ g\ m^{-2}$  and lower mean  $P_1$  to 11%. We have also assumed that no assimilate formed before the date of first labelling was later transferred to the grain. Inspection of Fig. 1 shows this to be incorrect, but the small total dry weights at first labelling mean the amounts of assimilate neglected are small. The transfer to the grain of assimilate formed as early as 27 d before anthesis (Fig. 1a) may be associated with the transfer of leaf nitrogen in the form of protein.

Considering this correction to  $GDW_2$  under regime I, the values of  $GDW_1 + GDW_2$  agree closely with the observed grain yield (Table 2). Also the figure of 13% for irrigated wheat is similar to that of 12% for an irrigated wheat crop determined with  $^{14}CO_2$  by Lupton<sup>3</sup>, and to values which can be calculated with our procedure from the extensive results of Birecka and Dakic-Wlodkowska<sup>8</sup>, albeit obtained with wheat grown in pots. An independent upper estimate of the contribution of pre-anthesis assimilate in the case of adjacent irrigated crops of Yecora 70 at CIANO is given by the quantity of sugar stored in stems at anthesis. This amounted to  $50\ g\ m^{-2}$  (15% stem sugar;  $320\ g\ m^{-2}$  stem tissue), to which should be added leaf protein transfer to the grain, for these purposes set equal to the decrease, anthesis to maturity, in leaf lamina dry weight, amounting to  $40\ g\ m^{-2}$  ( $200\ g\ m^{-2}$  of green leaf lamina tissue, 20% decrease in dry weight excluding leaf loss). The total available material thus estimated ( $90\ g\ m^{-2}$ ) agrees well with the value of  $GDW_1$  of Table 2 ( $69\ g\ m^{-2}$ ).

Table 2 makes possible a separate estimate of  $P_1$  based on the decline in non-grain dry weight after anthesis ( $\Delta TDW_2$  less

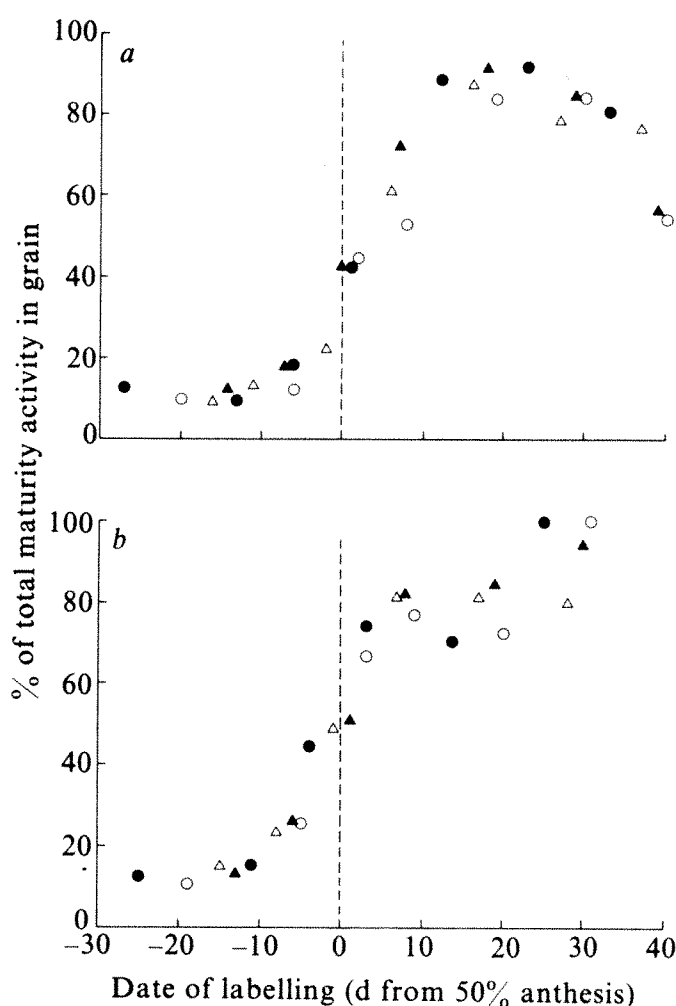

Fig. 1 The fraction at maturity of total crop  $^{14}C$  found in the grain as a function of the time (d from anthesis) when the  $^{14}CO_2$  was assimilated; a, frequently watered, (I); b, droughted, (D); Yecora 70 (●), Ciano (▲), CM67 (○) and WI 2198 (△).  $^{14}CO_2$  assimilation involved placing a clear polyethylene chamber over  $1.08\ m^2$  of crop. Into the chamber  $100\ \mu Ci$  of  $^{14}CO_2$  was introduced. The chamber remained closed and was stirred with a fan for 10 min. Labelling was carried out within 3 h of noon. At maturity, a  $0.3\ m^2$  quadrat was cut from each region previously labelled and the specific activity of oven dried subsamples were determined by combustion, trapping of the  $^{14}CO_2$  in a liquid scintillation mixture and counting.

Table 1 Grain yield and yield components in the 1974–75 experiment at CIANO, Mexico

Species	Cultivar	Date of 50% anthesis	Grain yield ( $g\ m^{-2}$ )	Kernel weight (mg)
Frequently watered throughout (I)				
Wheat	Yecora 70	March 17	639	45
	Ciano 67	March 10	563	43
Barley	CM 67	March 4	609	49
	WI2198	March 6	610	54
Droughted during grain filling (D)				
Wheat	Yecora 70	March 15	293	30
	Ciano 67	March 9	293	32
Barley	CM 67	March 3	363	38
	WI 2198	March 5	349	40
s.e.m.			18	0.5

Plots were sown on 14 December 1974 and received moderate fertilisation ( $75\ kg\ ha^{-1}\ N$  and  $18\ kg\ ha^{-1}\ P$ ). A split plot design (main plot = water regime, sub plot = cultivar) with three replications was used. Each sub plot was  $15\ m \times 1.8\ m$ .

observed  $GDW$ ), as proposed by Gallagher *et al.*<sup>4,5</sup>. But the calculation suggests practically zero contribution in all situations of Table 2. This has been confirmed for irrigated wheat by other experiments with many cultivars at CIANO over several years (ref. 10 and R.A.F., unpublished). The apparent discrepancy when compared to the  $^{14}C$  results of Table 2 probably arises because the absence of net change in the non-grain dry weight after anthesis, does not preclude translocation of pre-anthesis assimilate to the grain, balanced by the accumulation of post-anthesis assimilate in non-grain parts. The fact that the fraction of  $^{14}C$  in the grain from post-anthesis labelling averaged only 0.78 (Fig. 1, Table 2) supports this explanation. Also sampling in other irrigated wheat crops at CIANO showed that from anthesis to maturity the dry weight of the peduncle and chaff increases, while that of the leaves and the remainder of the stem decreases. If these latter decreases are taken to reflect assimilate translocated to the grain, the contribution agrees reasonably well with the 13% value in Table 2.

Our results point to a smaller value of  $P_1$  than that reported by Gallagher *et al.*<sup>4,5</sup>. Notwithstanding the discussion of the preceding paragraph, it is likely that in many situations the method of these authors overestimates  $P_1$ , because the dry

**Table 2** Estimation of the proportion of grain yield derived from pre-anthesis assimilate ( $P_1$ )

Variable	Frequently watered		Droughted

TDW, total dry weight ( $\text{g m}^{-2}$ ); GDW, grain dry weight ( $\text{g m}^{-2}$ ). TDW measured by harvests ( $0.30 \text{ m}^2$  quadrat per sub plot) at dates corresponding to those when  $^{14}\text{C}$  labelling was carried out, and by harvest ( $1.80 \text{ m}^2$  per sub plot) at maturity; anthesis TDW estimated by interpolation, and the increase in total dry weight during the pre-anthesis ( $\Delta TDW_1$ ) and post-anthesis ( $\Delta TDW_2$ ) periods was calculated.  $F_1$  and  $F_2$  are the average proportions of total crop  $^{14}\text{C}$  at maturity in the grain for labelling in the pre- and post-anthesis periods, respectively, and were obtained from Fig. 1. The contribution to grain yield of pre-anthesis ( $GDW_1$ ) and post-anthesis ( $GDW_2$ ) assimilate in absolute terms ( $\text{g m}^{-2}$ ) are equal to  $F_1 \times \Delta TDW_1$ , and  $F_2 \times \Delta TDW_2$ , respectively. The pre-anthesis assimilate contribution as a percentage ( $P_1$ ) is given by  $100 \times GDW_1 / (GDW_1 + GDW_2)$ . The data were averaged for the two cultivars of each species.

\*Time (d) before anthesis of first  $^{14}\text{C}$  labelling date.

†Average of both water regimes used.

weight change in non-grain parts includes tissue, principally leaves, lost due to decay, wind and so on. At other sites in Mexico,  $P_1$  estimated with this method for various non-droughted wheat cultivars ranged from 12 to 98%<sup>11</sup>, and clearly increased as site rainfall and disease incidence increased. We believe this reflects tissue loss, which even at CIANO with no rain or disease amounted to at least  $100 \text{ g m}^{-2}$ . Consequently the results from Nottingham<sup>4,5</sup> may have overestimated the importance of the pre-anthesis contribution of assimilate to grain yield. Even in the most suitable conditions for the expression of this contribution in our experiment (well grown wheat crops, post-anthesis drought reducing kernel weight 30%), it amounted to only 27% of final yield or  $79 \text{ g m}^{-2}$  according to the  $^{14}\text{C}$  data.

This work was carried out with the cooperation of the International Maize and Wheat Improvement Centre, Mexico, and Cornell University.

## Physiological energetics of cock-crow

ALTHOUGH much is known about bird song in the behavioural context there is no exact information concerning the efficiency of the communication system itself in terms of energy usage. Little attention has been paid to study of energy relationships in animal communications. The domestic fowl (*Gallus domesticus*) is a convenient subject on which to make physiological measurements of the energy involved in sound production, because of its size and its readiness to make calls in the laboratory, and because of the sheer volume of sound it produces. I have made such measurements and report them here.

Cock-crow is visibly and audibly one of the most vigorous and spectacular forms of avian vocalisation. The maximum root-mean-square (r.m.s.) sound pressure level attained during the performance is equivalent to a value of 100 dB at a distance of 1 m (Fig. 1a). This corresponds to a peak value of 103 dB. This very impressive achievement is accompanied by enormous rises in air-sac pressure and air flow in the trachea (Fig. 1c, d). Pressure rises to  $60 \text{ cm H}_2\text{O} = 6 \times 10^4 \text{ dyn cm}^{-2}$  and averages  $55 \text{ cm H}_2\text{O} = 5.5 \times 10^4 \text{ dyn cm}^{-2}$ . Air flow reaches  $500 \text{ ml s}^{-1}$  and averages  $\sim 350 \text{ ml s}^{-1}$  during the cycle.

Compared with a normal expiration, these values represent increases of  $\sim 100$ -fold and 15-fold for pressure and flow respectively. This indicates that, concomitant with sound production, there is a rise in airway resistance of some 6–7-fold. This rise is attributed to a change in the configuration of the syrinx, the sound-producing organ, involving, amongst other things, a narrowing of the syringeal lumen by the intruding tympaniform membranes<sup>1–3</sup>. In keeping with this idea, Fig. 1b indicates that the pressure changes in the trachea are comparatively small and, therefore, that virtually the whole of the pressure head generated in the air sacs is spent during the passage of air through the syrinx.

The fluid energy losses in the syrinx are accounted for mainly by frictional dissipation, but also to a lesser extent by conversion of a part of the energy into the mechanical vibration of the external tympaniform membranes, and hence into airborne vibrations. It is possible to estimate approximately the efficiency of this conversion process, and therefore of the effectiveness of the lung air sac-syrinx apparatus as an audio-generator, by comparing the total fluid energy losses incurred by the effort with the amount of sound energy finally produced. The work performed in expelling air from the lung air sac system to the atmosphere is estimated by measuring graphically the area enclosed by the pressure-volume curve during a single crowing cycle (Fig. 2d). The volume curve is itself obtained by graphical integration of the linearised flow curve. The final figure is  $\sim 3.5 \text{ W s}$ . The duration of the crow is 2 s, so the average work rate is 1.75 W. This does not, however, represent total crowing effort since no account has been taken of the internal work of the expiratory muscles lost as contraction heat, and the external work done in moving the viscera enclosing the air sacs.

To calculate the sound energy radiated, the sound pressure level curve given in Fig. 1a is first re-drawn as an equivalent power curve ( $0 \text{ dB} = 2 \times 10^{-4} \text{ dyn cm}^{-2} = 10^{-19} \text{ W cm}^{-2}$ ) which is then integrated over the crowing cycle to yield the total energy per  $\text{cm}^2$  (Fig. 3). The resultant value, assuming a maximum r.m.s. sound pressure level of 100 dB, works out at  $\sim 9 \times 10^{-7} \text{ W s}$ . This is equivalent to an average sound reading throughout the cycle of 95 dB. The total area

**Fig. 1a**, Average sound pressure level, at a distance of 1 m, during crow. Recordings were made with a Brüel and Kjaer 4161 omnidirectional microphone connected to a Nagra 1V SJ recorder and levels were confirmed by a Brüel and Kjaer 2209 precision sound level meter. Recordings were passed through a Grass 7P3 fast integrator to give a display of the sound pressure waveform. Bars above indicate division of crowing cycle into sections: A<sub>1</sub>, A<sub>2</sub>, introductory; B, transitional; C<sub>1</sub>, plateau; C<sub>2</sub>, final kick. **b**, Pressure changes in trachea. **c**, Air-flow rate. The flow meter was implanted into the trachea 2 cm caudal to the larynx. The calibration is nonlinear. **d**, Pressure changes in interclavicular air sac. Flow and pressure measurements were made with Grass PT5 manometers. Scale bar, 1 s.

over which the sound is radiated is calculated approximately by assuming, as is done in the case of human speech<sup>4</sup>, that the sound isobars are arranged in front of the mouth as concentric hemispheres. At a distance of 1 m, the total area of such a hemisphere is  $\sim 6 \times 10^4 \text{ cm}^2$ ; therefore, the total energy radiating from the mouth is  $\sim 9 \times 10^{-7} \times 6 \times 10^4 \text{ W s} = \sim 0.054 \text{ W s}$ . The average sound power is therefore  $0.054/2 = 0.027 \text{ W}$  or 27 mW. This figure is approximately 27 times the maximum speech power radiated during very loud human conversation<sup>5</sup>.

The efficiency of the sound-producing process, measured as the ratio of sound to fluid power, is  $0.055/3.5 \times 100 = 1.6\%$ . The overall efficiency, given in terms of the ratio of sound output to total physical exertion measured by the energy consumption of the driving muscles, is less than

**Fig. 2** Calculation of efficiency of sound production process. **a**, Linearised flow wave form. **b**, Volume curve obtained by integration of (a). **c**, Air-sac pressure waveform. **d**, Air-sac pressure-volume curve obtained from (c) and (b). The area enclosed by the curve gives the fluid work done during a single crowing cycle, given by  $\int PdV = \text{work}$ .

1.6% since it also includes on the input side thermodynamic energy wastage in the contracting tissue and energy spent moving the viscera.

Songbirds are capable of generating sounds which seem to be much louder in proportion to their body size, and therefore in proportion to their power resources, than chickens (unpublished observations). The efficiency of the sound-producing process in these smaller birds therefore seems to be greater. This may be related to well-known differences in the structure of the syrinx<sup>6</sup>, particularly the assemblage of intrinsic muscles which the chicken syrinx altogether lacks, and which seems to be responsible for accurately regulating both the shape of the syrinx and the flow of air through it.

I know of no other estimates of the efficiency of sound production of birds. It is, however, interesting to compare the figures for the chicken with those given for certain insects which use an entirely different mechanism of sound production, based on the rubbing of one part of the body against another. Crickets of the family Gryllinae can pro-

**Fig. 3** Power curve (—), obtained from sound pressure curve (---). The total energy per  $\text{cm}^2$  is obtained by measuring the area beneath the power curve.

duce  $6 \times 10^{-2}$  mW of sound with an overall efficiency of 5% whilst the mole cricket *Gryllotalpa vineae* produces 1.2 mW with a remarkable efficiency of 30% (ref. 7). These insects are clearly more economical in their use of energy than the fowl in which the overall efficiency is probably no greater than 1%. Nothing definite can be said as to the position of songbirds on the efficiency scale, although it seems to be greater than 1%.

## Regeneration of endoderm by ectoderm isolated from mouse blastocysts

CELL determination can be described as the progressive restriction in developmental options during embryogenesis<sup>1</sup>. Mouse embryo cells, in particular, remain undetermined for a relatively long period, and the fate of cells seems to be labile throughout the period of cleavage<sup>2–4</sup>. Micro-surgical analysis of mouse blastocysts, however, has shown that the developmental potential of inner cell mass and trophoblast cells becomes restricted during blastocyst formation, so that neither of these early cell types retains the option of differentiating into the other<sup>5–7</sup>. We have now investigated whether the primary ectoderm, which forms in the inner cell mass on day 5 of gestation<sup>8,9</sup>, retains the option of differentiating into endoderm. We found that when ectoderm was isolated from mouse blastocysts by immunosurgery<sup>10</sup> it could regenerate an outer layer of endoderm during further culture. The capacity of isolated ectoderm to differentiate into endoderm depended both on the initial mass of the embryo and on the time that the ectoderm was isolated from the inner cell mass.

Viable ectoderm cells can be isolated from pre-implantation mouse embryos by immunosurgery of blastocysts and thin inner cell masses<sup>11</sup>. Ectoderm thus isolated and cultured on feeder layers for 1–22 d differentiates into mesodermal and ectodermal derivatives, although it does not reform visceral endoderm<sup>12</sup>. But because the development of the inner cell mass in intact blastocysts requires a critical mass of tissue<sup>13</sup>, we investigated the developmental potential of ectoderm with increased mass isolated from aggregation chimaeras.

The survival of ectoderms isolated from chimaeric embryos and incubated in our culture conditions depended strongly on the number of embryos used to form the chimaera (Table 1). Ectoderms isolated from single embryos and chimaeras composed of two embryos degenerated; most of the ectoderms from chimaeras composed of four embryos survived, although only a few of these regenerated an endoderm layer. Most ectoderms isolated from chimaeras composed of eight or 10 embryos, however, survived and regenerated an outer layer of endoderm cells (Table 1, Fig. 1a, b). These cells had the characteristic apical vacuoles and microvilli of visceral endoderm cells (Fig. 2a, b) of mouse embryos *in vivo*<sup>8,17</sup> and *in vitro*<sup>8,18</sup>.

Although isolated ectoderms seemed by phase contrast microscopy to be essentially free of contaminating endoderm cells, it was possible that some endoderm cells

Fig. 1 Regeneration of endoderm by ectoderm isolated from chimaeric mouse blastocysts. *a*, Ectoderm just after immunosurgery of isolated inner cell mass (24 h after late blastocyst stage) (phase contrast,  $\times 310$ ). *b*, Ectoderm cultured for 48 h after immunosurgery. END, endoderm layer. (Phase contrast,  $\times 310$ .)

survived immunosurgery and rapidly proliferated to form a new endodermal layer. To determine whether regenerated endoderm arose from contaminating endoderm cells, we labelled cells after the second immunosurgery with <sup>3</sup>H-thymidine, and compared the grain counts per nucleus in ectoderm and regenerated endoderm after 48 h of culture (Table 2). The dilution of <sup>3</sup>H-thymidine labelling indicates a turnover time of about 24 h for the DNA of these cells. Assuming that there is little re-utilisation of salvaged DNA<sup>19</sup>, these results indicate a cell-cycle time for both ectoderm and endoderm cells *in vitro* of approximately 24 h. Therefore there would have to be a substantial number of contaminating endoderm cells (about 24) to produce the mean number of endoderm cells (96) present at 48 h (Table 2). We serially sectioned nine ectoderms fixed just after immunosurgery and found an average of three (0,0,1,1,2,2,3,8 and 10) contaminating endoderm cells for each ectoderm. Even these few endoderm cells may not have survived, because isolated ectoderms commonly lost a few dead outer cells during the 24 h following immunosurgery. We conclude that there were too few viable contaminating endoderm cells to account for the final number of regenerated endoderm cells and that both the ectoderm and the endoderm present at the end of the experiment arose from the ectoderm cell population.

The time at which ectoderm was isolated from the

Table 1 Effect of number of embryos in chimaeric blastocysts on endoderm regeneration by isolated mouse ectoderm cells

No. of embryos in chimaera	Total no.	No. of degenerated ectoderms	Alive, no endoderm	Endoderm + ectoderm
2	14	14	0	0 (0%)
4	18	5	11	2 (11%)
8	19	1	7	11 (57.9%)
10	31	2	6	23 (74.2%)

Two-cell embryos were obtained from mated Dub:(ICR) mice (Flow Laboratories) after superovulation with pregnant mares' serum gonadotropin and human chorionic gonadotropin. They were cultured in modified standard egg culture medium as before<sup>13</sup>. At the four- to eight-cell stage, between two and 10 embryos were aggregated to form chimaeras in the presence of phytohaemagglutinin<sup>14</sup>. At the late blastocyst stage (96-h culture from the two-cell stage) inner cell masses were isolated by immunosurgery<sup>10</sup>, embryos were incubated in rabbit anti-mouse L-cell (NCTC Clone 929) serum (1:1 dilution for 25 min) and guinea pig complement (Gibco) (1:5 dilution for 45 min). Ectoderms were isolated by further immunosurgery after inner cell masses had been cultured for another 24 h in modified Eagle's basal medium<sup>15,16</sup> containing 5% foetal calf serum and 5% newborn calf serum. Ectoderms were cultured individually for 48–72 h in drops of medium, with or without paraffin oil, in bacteriological Petri dishes (Falcon) to prevent attachment and outgrowth of ectodermal cells on the substrate. They were scored for the presence of an endodermal layer under the dissecting microscope ( $\times 140$ ).

**Table 2** Grain counts on nuclei of  $^3\text{H}$ -thymidine-labelled cells before and after endoderm regeneration

Cell type	Hours cultured	No. of samples	Mean no. of cells per sample*	Mean % labelled	Mean no. of grains per nucleus $\pm$ s.e.m.
Ectoderm	0	2	292	74	$43.8 \pm 2.4$
	24	3	192	86	$17.7 \pm 1.4$
	48	2	253	67	$9.2 \pm 1.5$
Endoderm	24	1	109	61	$15.9 \pm 1.7$
	48	3	96	73	$9.1 \pm 2.6$

Two-cell embryos were cultured overnight and made into chimaeras (10 embryos each) as described in Table 1. Inner cell masses were obtained by immunosurgery from these embryos at the late blastocyst stage; ectoderms were obtained from inner cell masses after 24 h. Ectoderms were labelled with  $^3\text{H}$ -thymidine ( $10^{-2}$   $\mu\text{Ci ml}^{-1}$ , specific activity 45 Ci  $\text{mmol}^{-1}$ ) for 4 h, washed and cultured for the designated time before hypotonic treatment and fixation in glacial acetic acid and 95% ethanol (1:1) in watch glasses essentially as described<sup>20</sup>. At these concentrations of  $^3\text{H}$ -thymidine there was no effect on cell viability<sup>25</sup>. Autoradiographic exposure was for 3 d. Endoderm and ectoderm layers were separated before fixation by enzyme treatment as before<sup>21</sup>.

\*These numbers may be underestimates because of losses during separation or fixation.

inner cell mass by immunosurgery also strongly influenced its ability to regenerate endoderm. When ectoderms were isolated from inner cell masses 24 or 48 h after isolation of the inner cell masses from late blastocysts the ectoderms regenerated a layer of endoderm. But virtually all ectoderms isolated 72 h after isolation of inner cell masses from late blastocysts failed to regenerate endoderm, and instead they degenerated within 48 h of further culture (Table 3).

Our results show that the inner cells of the isolated

**Fig. 2** Thick section of ectoderm before and after endoderm regeneration. *a*, Ectoderm fixed and sectioned just after immunosurgery (24 h after late blastocyst stage) (bright field,  $\times 430$ ). *b*, Ectoderm cultured for 48 h after immunosurgery. Note complete outer layer of endoderm and central cavity containing cell debris (bright field,  $\times 430$ ). Ectoderms were isolated from chimaeric blastocysts as described in Table 2. *a*

*b*

mouse inner cell mass—the embryonic ectoderm—retain the capacity to differentiate *in vitro* into endoderm for a period well beyond the time that endoderm differentiation normally occurs. Because isolated ectoderms in our experiments regenerate visceral endoderm 48 h after the late blastocyst stage, there seems to be a period of at least 2 d before ectoderm of the mouse inner cell mass undergoes any restriction in its developmental fate. Although failure of ectoderm to regenerate endoderm when isolated after 72 h of culture could imply that ectoderm itself is sensitive to the immunosurgery and culture procedures, we consider this possibility unlikely because of the high incidence of development when it is isolated at earlier stages (Table 3). We conclude that loss of the ability to form visceral endoderm is due to a determinative event between 48 and 72 h after the late blastocyst stage.

By contrast, the developmental potential of visceral endoderm cells seems already to be restricted at the late blastocyst stage. Endoderm cells that are transferred to host blastocysts colonise only the extra-embryonic regions, while ectoderm cells colonise the entire conceptus<sup>6</sup>. Also, visceral endoderm isolated from mouse and rat egg cylinders fails to survive when transferred to ectopic sites<sup>21-23</sup>. The definitive endoderm of the foetus therefore does not seem to arise from the visceral endoderm<sup>6,21-23</sup>.

The major difference between our approach and that of others who did not observe endoderm regeneration by isolated ectoderms<sup>11,12</sup> was our use of chimaeric embryos to increase the mass of the isolated tissues and our prevention of ectoderm attachment to substrate. We interpreted the disintegration of ectoderms isolated from single or paired embryos as an indication that survival of functional inner cells requires a critical mass of tissue which does not exist once trophoblast and endoderm cells are destroyed by immunosurgery. It may be possible, however, to circumvent this requirement in part by

**Table 3** Effect of ICM culture time on formation of endoderm by isolated ectoderms

Hours of culture of isolated ICM	Total no. of ectoderms	No. of degenerated ectoderms	No. of live ectoderms without endoderm	No. of ectoderms with endoderm
24	28	0	6	22
48	14	0	0	14
72	31	29	1	1

Two cell embryos were cultured overnight and chimaeras (10 embryos each) were formed. Inner cell masses (ICM) were isolated by immunosurgery from blastocysts (Table 1) and cultured for various times before isolation of ectoderm by immunosurgery. Growth was scored after 48 or 72 h. Data was pooled from three experiments.

providing a feeder layer of fibroblasts<sup>12</sup>. The failure of ectoderm even from chimaeras of 10 embryos to survive isolation after 72 h of culture implies either that endoderm has an essential, perhaps nutritional function at this time or that after losing the ability to form endoderm, ectoderm cells must attach to survive or to differentiate further. There did not seem to be any obvious morphological change in the ectoderm, however, that correlated with the loss of ability to regenerate endoderm after 72 h in culture. After 24 h of culture isolated inner cell masses have a homogeneous core of ectoderm cells; after 48 and 72 h, the ectoderm has developed into a pseudostratified columnar epithelium surrounding a proamniotic cavity. The cavity, however, increases from approximately 30  $\mu$ m to 100  $\mu$ m in diameter during this time<sup>26</sup> (and unpublished results).

In view of our results with mouse ectoderm isolated 24–72 h after the late blastocyst stage, it seems that the ability to form visceral endoderm, a trait shared by clonal embryonal carcinoma cells<sup>24</sup>, is lost at a time (7–8 equivalent days of gestation) when the embryonic ectoderm can still develop into all three definitive germ layers when it is transferred to ectopic sites<sup>22,23</sup>.

We thank Kitty Wu for assistance, and Gail Martin, Michael Sherman and Davor Solter for comments. This work was supported by the US ERDA.

## Non-metastasising variants selected from metastasising melanoma cells

THE cell surface may be involved in the metastatic process of cancer cells<sup>1</sup>. To determine whether membrane properties influence or reflect the metastasising capacity, it is essential to have metastasising and non-metastasising variants of the same tumour. Lectins which bind specifically to surface carbohydrates<sup>2</sup> have been used successfully as selective agents to obtain cells with membrane carbohydrate alterations<sup>3–5</sup>. We

Table 1 *In vitro* characterisation of melanoma variants

Cells	Selection	Surviving colonies*	%Agglutination†	% WGA binding‡
F-1	—	—	97	100
Wa-2	2nd	10	85	80
Wa-3	3rd	50	66	69
Wa-4	4th	> 200	24	62

\*Surviving colonies growing out from  $2 \times 10^6$  cells following incubation for 10 d in selective medium (100  $\mu$ g ml<sup>-1</sup> WGA in Eagle's minimal essential medium supplemented with 10% foetal calf serum) and 2 weeks in normal medium without WGA.

†No. of agglutinated cells/no. of total cells  $\times$  100% following incubation of  $1 \times 10^6$  cells per ml with 10  $\mu$ g WGA per ml for 5 min at room temperature<sup>7</sup>.

‡F-1 control cells (100% binding) bound 275.5 c.p.m. per  $\mu$ g cell protein after 5 min of incubation of  $1 \times 10^6$  cells per ml with 5  $\mu$ g <sup>125</sup>I-WGA per ml at 4 °C (specific activity  $4.8 \times 10^4$  c.p.m. per  $\mu$ g WGA—supplied by A. Rapin).

have selected variants of melanoma cells for surface differences in using toxic concentrations of lectins in the hope that such variants would exhibit different metastasising capacities. We report here the isolation of variants from metastasising melanoma cells resistant to toxic concentrations of wheat germ agglutinin (WGA). These variants show reduced to a loss of metastasising capacity and altered surface properties.

Mouse B-16 melanoma cells (adapted to grow in tissue culture<sup>6</sup>; supplied by Dr I. J. Fidler, designated as F-1) were maintained in tissue culture for 10 d in selective medium containing WGA at 100  $\mu$ g ml<sup>-1</sup>. The WGA-containing medium was then replaced with normal medium and the surviving cells were allowed to grow into discrete colonies in the ensuing 2–3 weeks. All of the resulting six individual colonies were isolated as clones. One of these six clones was further subjected to the same selection procedure successively to produce first Wa-2, then Wa-3 and Wa-4 clones. Table 1 shows that with each additional selection, more cells survived the selective pressure. This increased resistance to the toxic effects of WGA was clearly confirmed in Fig. 1 which compares the growth rates of the parental line F-1 and one of the Wa-4 lines in different concentrations of WGA.

The metastasising capacity was tested by injecting  $5 \times 10^4$  cells intraperitoneally (i.p.) and scoring the resulting tumours in various organs 2–3 weeks later. All animals developed peritoneal tumour masses with ascites and died within 2–4 weeks of injection. Parental cells metastasised in 92% of the animals to mediastinal and mesenteric lymph nodes, and in 58% to liver, kidneys and lungs, as shown in Table 2. In contrast, Wa-2 cells showed a greatly decreased metastasising capacity, while Wa-3 and Wa-4 cells failed to metastasise at all.

Tumorigenicity was tested by injecting  $2 \times 10^5$  cells intravenously (i.v.) and 2–3 weeks later examining the tumour nodules in the lungs, generally the only site where tumours developed after i.v. injection. With successive WGA selections, the metastasising capacity of the variants decreased before tumorigenicity was reduced (Wa-2) while tumorigenicity began to decrease only at the point where no metastases could be detected (Wa-3 and Wa-4) (Table 2). This decreased tumorigenicity was further confirmed by injecting the tumour cells subcutaneously to eliminate the possible complicating factors affecting the survival of circulating tumour cells. Preliminary experiments showing the same pattern in nude mice rule out the possibility that the decreased tumorigenicity was simply due to an alteration in histocompatibility antigens.

Substantial differences in growth rates could influence the results of assays for tumorigenicity and metastasising capacity. But, although *in vivo* growth rates have not yet been assessed, all cell lines showed similar growth rates in tissue culture, with generation times in the range 14–16 h (Fig. 1).

Some of the surface properties of the variants were shown to be different from the parental cells as reflected by a substantial decrease in agglutinability with WGA (Table 1). In addition,

Fig. 1 Growth curves of parental and variant melanoma cell lines in the presence of WGA. Parental F-1 (○) and a Wa-4 variant (●) were grown in 0 (---), 33 (—), 50 (· · ·) and 75 μg WGA per ml (---) in Eagle's minimal essential medium with 10% foetal calf serum on 10 mm × 35 mm Falcon plastic culture dishes. WGA was added on day 1. Cells were removed daily with trypsin-EDTA and counted in Coulter counter. Each point represents the average value of duplicate dishes.

a decrease in lectin binding was also observed with some lines (Table 1).

The original metastasising line provided by Fidler and the completely non-metastasising variants described here display a maximal difference in metastasising capacity, while they exhibit no significant difference in growth rates *in vitro*. A detailed study of such lines should shed some light on the basic mechanisms underlying the process of metastasis.

By successively passing the B-16 cells through the lungs of the animals, Fidler<sup>8</sup> established lines showing a five- to tenfold increase in metastasising capacity which was defined in his experiment as the number of pulmonary nodules developed after i.v. injection of the tumour cells. Efforts to find surface differences with these lines have been rather disappointing<sup>9</sup>. This could have been because the quantitative difference in metastasising capacity may not have been large enough to allow the detection of biochemical alterations.

Comparison of the properties of metastasising and non-metastasising variants showed metastasising cells to be invasive,

where the non-metastasising variants were not invasive. The following preliminary observations were further noted. The non-metastasising variants displayed the greater homotypic adhesion. With successive WGA selection, there seemed to be a gradual increase in the organisation of some of the microstructural elements, from the parental line showing disorganised pattern to Wa-4 lines showing well organised stress fibres. Peptide patterns seen with slab gel electrophoresis following surface labelling were basically similar for the different cell types with the exception of one or two bands which were diminished in the non-metastasising variants.

We thank J. Jenkins and K. Vogel for technical assistance and A. Matter (Hoffmann La Roche) for providing mice. This work was supported by a Swiss National Foundation grant (3.720.76).

## Activation of complement by variant-specific surface antigen of *Trypanosoma brucei*

ANTICOMPLEMENT factors have been shown to occur in certain parasitic infections of man and animals. Hammerberg *et al.*<sup>1</sup> demonstrated the presence of a factor from *Taenia taeniaeformis* capable of activating complement through the alternate pathway. Similar findings have been reported for a substance in the cercarial coat of *Schistosoma mansoni*<sup>2</sup>. In trypanosomiasis, no such parasitic activity has been reported although hypocomplementaemia has been recognised as a consistent feature of the disease. Marked reductions in complement C4 and C3 were observed in infections with *Trypanosoma lewisi*<sup>3</sup>, *Tr. rhodesiense*<sup>4</sup> and *Tr. congolense*<sup>5</sup>. One possible mechanism is that the decrease of these complement components results from activation by antigen-antibody complexes. Deposits of immunoglobulins and complement have been demonstrated in kidneys of mice infected with *Trypanosoma brucei*<sup>6,7</sup> and monkeys infected with *Tr. rhodesiense*<sup>4</sup>. We present here evidence for an alternative mechanism operating through direct activation of human complement, via the classical pathway, by an isolated variant-specific surface antigen of *Tr. brucei*.

*Tr. brucei* grown in normal rats was isolated from infected blood using the method of Lanham<sup>8</sup>. In an initial experiment four preparations were used. The first fraction contained live trypanosomes; the second fixed parasites (1% formalin) and the third and fourth were 12,000g (30 min) supernatant and pellet fractions from trypanosomes sonicated on ice for 1 min. All these fractions were tested for the ability to activate human complement in a haemolytic assay<sup>9</sup>. The results showed that each of the four fractions depressed the provided CH<sub>50</sub> (CH<sub>50</sub>, 50% haemolytic dose) by at least 40% (Table 1). Decomplementation also occurred when bovine or rat serum was used as the source of complement. Similar supernatant and pellet fractions derived from *Tr. congolense* were also active (Table 1). Since these preparations may have contained antigen-antibody complexes, analogous fractions were derived from cloned organisms grown in lethally-irradiated mice (900 R) and tested as before. The

**Table 1** Ability of various preparations from *Tr. brucei* and *Tr. congolense* to depress complement activity

Parasite	Preparation	% Consumption of CH <sub>50</sub> per ml
<i>Tr. brucei</i>	Live	57
	Formalised	53
	Supernatant	41
<i>Tr. congolense</i>	Pellet	58
	Supernatant	47
	Pellet	52

Each preparation used in the assays was derived from  $4 \times 10^7$  parasites and contained in 0.2 ml of veronal-buffered saline. Human serum, obtained from normal donors, was adjusted to provide approximately 10 CH<sub>50</sub> per ml. One ml of the diluted serum was mixed with each fraction or buffer and incubated for 1 h at 37 °C. After incubation the particulate substances were removed by centrifugation and the residual complement titre (CH<sub>50</sub> per ml) determined according to the method of Rapp and Borsos<sup>9</sup>. Sheep cells, sensitised with rabbit haemolysin, were used at a concentration of  $2.5 \times 10^8$  per ml.

results were similar, indicating that the observed utilisation of complement was independent of immune complexes.

The results obtained using the supernatant fraction suggested that the variant antigen, a major soluble glycoprotein, could be involved. To examine this hypothesis a variant specific surface antigen from *Tr. brucei*, clone 052, was prepared using the method of Cross<sup>10</sup>. The parasites were grown from a stabilate in lethally-irradiated mice, followed by passage for 2–3 d in normal rats and then isolated. The purified glycoprotein had a *pI* of 6.9 and ran as a single band of 64,000 apparent molecular weight in sodium dodecyl sulphate (SDS)–7.5% polyacrylamide gels. These values are in agreement with published data<sup>10</sup>. No host proteins were detected in the preparation by immunodiffusion. This variant antigen, tested in a haemolytic assay as before, caused extensive de complementation using as little as 50 µg protein. A dose–response curve indicated that the de complementation was a logarithmic function of the amount of protein added (Fig. 1). Bearing in mind the extensive differences postulated among *Tr. brucei* surface antigens<sup>10</sup>, a second variant antigen from clone 055 was tested. This glycoprotein was also active.

A further series of experiments was performed to determine the mode of activation of complement. It has been shown by Fine *et al.*<sup>11</sup> that, since the classical and properdin pathways of complement activation have different cation requirements (calcium and magnesium for the former and only magnesium for the latter), EDTA and EGTA may be used to distinguish between the two. EDTA chelates both Ca<sup>2+</sup> and Mg<sup>2+</sup> ions while EGTA binds Ca<sup>2+</sup> effectively but has little affinity for Mg<sup>2+</sup>. In the following experiment, 270 µg of the purified antigen were incubated, for 1 h at 37 °C, with 1 ml of normal human serum (NHS, approximately 320 CH<sub>50</sub> per ml) made 10 mM with either EDTA or EGTA. The residual complement activity was measured as before. The results showed that there was no de complementation in the presence of these chelators, suggesting that activation of complement proceeds by the classical pathway. But, a particulate fraction (1.2 mg protein) prepared from the same clone and tested similarly, depressed complement activity by 72% in the presence of EGTA.

**Fig. 1** A sample of 1 ml of diluted normal human serum (10 CH<sub>50</sub> ml<sup>-1</sup>), was incubated with various amounts of the variant antigen, or buffer, for 1 h at 37 °C. The residual haemolytic titre (CH<sub>50</sub> ml<sup>-1</sup>) was determined using the method of Rapp and Borsos<sup>9</sup>.

This would indicate the presence, in the trypanosome, of another factor capable of activating the alternate pathway.

To confirm the results obtained using specific metal chelators, C1, C4, C2 and C3 activities were measured. The variant antigen was incubated with normal human serum and the residual activities of these individual components estimated using methods described by Rapp and Borsos<sup>9</sup>. The titres were calculated as the number of effective molecules per ml of the individual component being assayed<sup>9</sup>. The results showed preferential utilisation of C1, C4 and C2, with only a moderate change in C3, indicating classical pathway of activation (Table 2).

To test the ability of the variant antigen to cause permeability changes in the skin normal female rats, shaved over the dorsal region were given 0.5 ml of 1% brilliant blue R 10 min before intradermal inoculation of 20 µg of the variant antigen, histamine (5 µg), or buffer. Marked extravasation of dye occurred within 10 min at sites inoculated with variant antigen or histamine. Control sites showed only minimal extravasation of the dye at the site of needle trauma. Administration of an antihistamine (mepyramine maleate 30 mg per kg body weight), before the intradermal inoculations completely abolished the reaction to histamine and to variant antigen. These results suggested that variant antigen mediated production of anaphylotoxins had occurred.

Our observations indicate that complement activation by variant antigen, possibly released during the destruction of trypanosomes at each parasitaemic wave, might be an important contributory factor in depression of complement levels in man<sup>12</sup>

**Table 2** Consumption of some individual complement components in normal human serum incubated with a variant antigen of *Tr. brucei*

Component assayed	Effective molecules provided	Cellular intermediate	Source of other components	% consumption
C1	$7.4 \times 10^{12}$	EAC4hu*	C2hu, gp C-EDTA 0.04 M	61
C4	$4.8 \times 10^{12}$	EAC1gp†	C2hu, gp C-EDTA 0.04 M	95
C2	$5.0 \times 10^{10}$	EAC1gp4hu	gp C-EDTA 0.04 M	90
C3	$1.4 \times 10^{11}$	EAC1gp4hu	C2, 5, 6, 7hu C8, 9, gp	11

Normal human serum was diluted with gelatin-veronal buffer containing 0.0015 M Ca<sup>2+</sup> and 0.0005 M Mg<sup>2+</sup> to provide the above effective molecules of individual components. One ml was incubated with 270 µg of the variant antigen, or buffer alone, for 1 h at 37 °C. The residual activities of individual components were then assayed using cellular intermediates and functionally pure components from Cordis Laboratories, Miami. The cellular intermediates were used at a concentration of  $1 \times 10^8$  cells per ml.

†gp, guinea pig.

and in animals suffering from trypanosomiasis. Since recent experiments have shown that complement is essential in antibody-mediated destruction of trypanosomes<sup>13</sup>, the hypocomplementaemic state resulting from the activation would favour the survival of the parasites.

Papamichail *et al.*<sup>14</sup> and others have shown that complement plays a part in antibody production to thymus-dependent antigens. Whether or not trypanosome antigens are thymus-dependent is uncertain. But, such low complement levels are likely to affect the antibody response of the host to trypanosome antigens.

Finally, evidence of increased vascular permeability in the form of perivascular oedema and swelling and degeneration of vessel walls, is a consistent pathological finding in animals infected with *Tr. brucei*<sup>15,16</sup> and *Tr. congolense*<sup>17</sup>. While these changes might result from antigen-antibody reactions, our observation suggesting interaction between variant antigen and complement, producing a vascular permeability factor, should also be considered as a mechanism in the pathogenesis of these and other lesions which occur in African trypanosomiasis<sup>18</sup>.

We thank Venny Shitakha, G. W. Mpimbaza and J. Mayanja-Katende for technical assistance.

## Induction of epidermal transglutaminase by hydrocortisone in chick embryonic skin

WE demonstrated previously that the epidermal cells of chick embryos are induced to differentiate by glucocorticoids<sup>1,2</sup>. Hydrocortisone ( $0.01 \mu\text{g ml}^{-1}$ ) added to a serum-free chemically-defined medium produced an intense keratinised layer over the uppermost cells<sup>3</sup> and many tonofilaments within the basal and intermediate cells<sup>4</sup> of the epidermis after 4 d in culture of 13-d-old embryonic chick tarsometatarsal skin. Within 12-16 h of hydrocortisone addition it is possible to show the synthesis of a urea-mercaptoethanol soluble, glycine-rich and metabolically stable epidermal structural protein<sup>5</sup> and the accumulation of a urea-mercaptoethanol insoluble epidermal protein(s)<sup>4</sup>. These changes of protein metabolism induced by hydrocortisone paralleled those seen during *in ovo* keratinisation of the epidermis<sup>4,5</sup>. The amino acid composition of the two proteins was very similar suggesting that the soluble protein is converted to the insoluble one in the process of epidermal keratinisation of chick embryonic skin. We show here that the levels of transglutaminase (TG), an enzyme that possibly mediates cross-linking of keratinous polypeptide chains by a  $\epsilon$ -( $\gamma$ -glutamyl) lysine bond<sup>6-8</sup>, increases both during *in ovo*

development of the epidermis and during hydrocortisone-induced *in vitro* keratinisation of chick embryonic cultured skin.

Table 1 shows that TG activity in the undifferentiated epidermis of 13-d-old embryonic chick skin was only 7 mU per mg protein, compared with 53 mU per mg protein in the heavily keratinised epidermis of 19-d-old embryonic chick skin. Furthermore, when 13-d-old embryonic chick skin was cultured for 4 d in a chemically-defined medium with or without hydrocortisone, TG activities of the steroid-treated epidermis were 52-107 mU per mg protein, whereas the activity in control epidermis was only 3-30 mU per mg protein. Figure 1 shows that after culture for 20 h the specific activities of TG in the treated epidermis were seven times those in control tissue. During the cultivation epidermal TG activities started to rise sharply after incubation for 8 h in the presence of the steroid. But, when actinomycin D was added at  $4 \mu\text{g ml}^{-1}$ , a concentration that blocks more than 99% of RNA synthesis, no increase of TG activity was observed, indicating that TG induction by hydrocortisone requires RNA synthesis. A similar effect was seen with cultured chick embryonic neural retina<sup>9</sup>; hydrocortisone added to the medium induced glutamine synthetase followed by *in vitro* differentiation of the tissue and actinomycin D abolished the enzyme induction. Further analyses are necessary to clarify whether hydrocortisone stimulates the synthesis of TG mRNA in our skin culture; however glucocorticoids were reported to induce the synthesis of specific enzymes through the increased synthesis of their mRNA for cultured rat hepatoma cells<sup>10</sup> and for rat liver<sup>11</sup> while many other kinds of cells, tissues and organs require the steroids for induction or maintenance of their differentiated function<sup>12</sup>.

It should be noted that hydrocortisone induced TG several hours before the induction of soluble epidermal structural protein and this earlier increase of the enzyme activity coincided exactly with that seen during *in ovo* development of the epidermis (data not shown). These findings suggest that the enzyme may be involved in a series of finely organised processes of epidermal cell differentiation. But more detailed studies are required to test the hypothesis that soluble structural proteins are cross-linked or polymerised by epidermal TG to insoluble high molecular ones composing tonofilaments to culminate in keratinisation of epidermal cells. One of the problems under study is whether

**Fig. 1** Changes of the specific activities of epidermal transglutaminase (TG) of 13-d-old chick embryonic skin during the cultures in the presence or absence of inducer and suppressor. Methods of skin cultivation and TG determination were essentially as described in Table 1. One of the pair-mate explants after preculture for 1 d was incubated with hydrocortisone (HC;  $0.01 \mu\text{g ml}^{-1}$ ) and the other with the steroid plus actinomycin D (Boehringer Mannheim;  $4 \mu\text{g ml}^{-1}$ ). ■, Epidermal TG activities of the skin cultured without HC; ●, epidermal TG activities of the skin cultured with HC; ▲, epidermal TG activities of the skin cultured with HC plus actinomycin D. Values of each point are the mean of duplicated determinations for a pool of five sheets of the epidermis.

			52 52

Pair-mate explants from right and left tarsometatarsal regions of 13-d-old chick embryos were cultured for 4 d in a chemically-defined medium, BGJb supplemented with ascorbate, by the Millipore filter-roller-tube method<sup>3</sup>. One of the pair-mate explants was cultured in the medium containing hydrocortisone sodium hemisuccinate (Upjohn) 0.01 µg ml<sup>-1</sup>, and the other was cultured in medium without the steroid. The epidermis of cultured explants and that from the same part of chick embryos in the normal course to hatching were each obtained by incubating the skin at 37 °C for 10–40 min in Eagle's minimum essential medium supplemented with 10% calf serum and 900 PU per ml Dispase I (a bacterial neutral protease, Godo Shusei). Crude enzyme preparation from the epidermis was prepared by a modification of the method of Ogawa and Goldsmith<sup>6</sup>. The epidermis was homogenised in 10 mM Tris-acetate (pH 7.5)–1 mM EDTA by the use of a glass homogeniser with five strokes at intermediate speed. This and all further operations were at 0–4 °C. The homogenates were centrifuged for 30 min at 12,000g at 4 °C. The sediments were extracted two additional times in the same manner and the supernatants were combined. The supernatant fluid taken in a cellulose tubing (Visking) was concentrated with sucrose. The concentrated supernatant was dialysed against a buffer of 5 mM Tris-acetate (pH 7.5) with 1 mM EDTA. Transglutaminase activity was assayed for the dialysed supernatant as an enzyme preparation by measuring the incorporation of [1,4-<sup>14</sup>C]putrescine (Radiochemical Centre, Amersham; 60 mCi mmol<sup>-1</sup>) into α-casein (according to Hammarsten; Merck) after the method of Goldsmith and Martin<sup>13</sup>. The assay mixture contained 0.11 M glycine-NaOH (pH 10.0) with 0.56 mM EDTA, 10 mM CaCl<sub>2</sub>, 5 mM dithiothreitol, 9 µM labelled putrescine and 0.15% casein. Aliquots (0.5 ml) of the assay mixture were added to 100 µl of each enzyme preparation. The mixtures were incubated for 30 min at 37 °C. The reaction was stopped by the addition of 0.6 ml of 10% trichloroacetic acid. The precipitate was collected on Whatman GF/C filters and the precipitated radioactivity was measured in toluene containing 0.4% 2,5-diphenyloxazole (Dotite) and 0.01% 1,4-bis(2-(5-phenyloxazolyl))-benzene (Dotite) with a Aloka Liquid Scintillation Spectrometer. An enzyme unit is defined as the amount of enzyme that catalyses the incorporation of 1 nmol of putrescine into casein in 30 min. Specific activity is defined as enzyme units per mg protein. Protein was measured by the technique of Lowry *et al.*<sup>14</sup> with bovine serum albumin as a standard. Values are averages of duplicated determinations for a pool of five sheets of the epidermis.

\*Mean ± standard error. Figures in parentheses represent the number of separate experiments.

there are much more ε- (γ-glutamyl) lysine cross-links in the insoluble protein than in the soluble protein of the chick embryonic epidermis.

## Ionophore-mediated calcium influx effects on the post-synaptic muscle fibre membrane

THE physiological chemotransmitter acetylcholine and its structural analogues such as carbamylcholine are capable of producing a sustained blockade of neuromuscular transmission when applied to the neuromuscular junction for prolonged periods. This neuromuscular blockade is not due to a depolarisation of the postsynaptic muscle fibre membrane but rather is generally ascribed to the inactivation, or 'desensitisation' of cholinergic receptor molecules in the postsynaptic membrane<sup>1,2</sup>. Various kinetic models involving agonist, and receptor

molecules postulated to exist in different conformational states, have been proposed to account for the time course of the desensitisation process<sup>3,4</sup>. These models do not incorporate the acceleration of desensitisation by calcium ions<sup>4,5</sup> and they do not predict correctly the observed effects of certain cholinergic antagonists on desensitisation. Consequently, alternative models for desensitisation have been proposed. In one of them calcium ions accumulate at the interior surface of the post-synaptic membrane and bind to the cholinergic receptors, thereby causing desensitisation by producing or sustaining some inactive receptor conformation<sup>6</sup>. We tested the model for desensitisation which involves internal calcium binding. This was accomplished by facilitating calcium ion flux across the post-synaptic membrane using the divalent cation ionophore A23187, while simultaneously producing a rapid desensitisation with iontophoretic application of carbamylcholine. Our results provide further evidence that calcium ions are a significant factor in the molecular mechanism of desensitisation.

A23187 is a carboxylic ionophore with high affinity for divalent cations and little or no affinity for univalent cations<sup>7</sup>. It is capable of transporting calcium ions across otherwise highly impermeable artificial and biological membranes by an essentially electroneutral process<sup>8</sup>. As a probe in research on contractile systems, A23187 has been used to release stored calcium from isolated sarcoplasmic reticulum vesicles<sup>9,10</sup>. A23187 has also been reported to increase the twitch tension of barnacle muscle fibres without altering the electrical properties of the fibre membranes<sup>11</sup>.

Using established single fibre stimulation and recording techniques, we investigated the effects of a wide range of A23187 concentrations on the electrical behaviour of frog (*Rana pipiens*) cutaneous pectoris or sartorius muscles employed in our desensitisation experiments. Resting and action potentials were recorded at junctional and extra-junctional sites and in addition, miniature end-plate potentials (m.e.p.s) were recorded at the junctions.

Because A23187 is only slightly soluble in aqueous media such as frog Ringer solution, a stock solution was prepared in 100% ethanol and appropriate quantities were added to the Ringer solution. Control experiments showed that ethanol, at the highest concentrations involved (0.5%), had an insignificant effect on the resting potentials, action potentials and m.e.p. frequencies recorded from muscle fibres. A small increase in

**Table 1** Effects of bath-applied A23187 on miniature end-plate potential frequency

Expt	A23187 Concentration ( $\mu\text{M}$ )	Exposure time (min)	M.e.p. frequency (Hz)	No. of fibres
1	0 (control)	Continuous	$0.30 \pm 0.22^*$	10
	0.28		$0.57 \pm 0.13$	12
2	0 (control)	Continuous	$1.1 \pm 0.7$	6
	0.56		$1.4 \pm 1.3$	6
3	0 (control)	10	$2.0 \pm 0.3$	10

4	0 (control)	5	$1.3 \pm 0.6$	10
	7.5		$6.0 \pm 3.9$	14

Control solution was HEPES buffered Ringer solution (composition: 112.4 mM  $\text{Na}^+$ , 2.5 mM  $\text{K}^+$ , 1.8 mM  $\text{Ca}^{2+}$ , 117.1 mM  $\text{Cl}^-$ , 3.0 mM HEPES buffer; pH, 7.4). A23187 solutions contained 0.02, 0.04, 0.2 and 0.5% ethanol respectively.

\*Mean  $\pm$  s.d.

m.e.p. frequency was obtained when the Ringer solution contained 1% ethanol; this agrees with published data on the effects of alcohol on neuromuscular systems<sup>12,13</sup>. In our experiments involving the production of desensitisation the alcohol concentration never exceeded 0.04%. Control experiments showed that at this concentration ethanol had no effect on desensitisation.

Two different methods were used to apply the ionophore to the muscle fibres in both electrical behaviour studies and desensitisation studies. In the first method A23187 stock solution was added to HEPES-buffered Ringer solution (see Table 1 for composition) forming a suspension of the ionophore. After making recordings from muscle fibres bathed in ionophore-free Ringer solution, the low concentration A23187 solutions were continuously bath-applied during which time a second group of recordings was obtained. With solutions containing high concentrations of A23187 (3–15  $\mu\text{M}$ ) application to the muscle was limited to a few minutes following which the bath was changed to ionophore free Ringer solution and thereafter additional recordings were made. This procedure was used to avoid production of 'retraction clots' and other mechanical disturbances presumably caused by an excessive ionophore-promoted increase in  $\text{Ca}^{2+}$  influx which could lead to activation of the contractile system.

Many fibres exposed to A23187 for 5–10 min at concentrations above 8  $\mu\text{M}$  contracted irreversibly (formed retraction clots) and others twitched spontaneously for several minutes after the ionophore was removed from the bath. Retraction clots were also produced in fibres perfused with 6  $\mu\text{M}$  to 8  $\mu\text{M}$  A23187 solutions.

In the second method of applying the A23187, a quantity of the ionophore stock solution was added to calcium-free Ringer solution. A small region of a muscle immersed in ordinary Ringer solution was then microprefused with the Ca-free A23187 solution for 1–2 min. Recordings were made at the perfusion sites after allowing the ordinary Ringer solution to diffuse back into the ionophore treated region. This perfusion method was used in order to avoid mechanical artefacts (see above).

From bath application experiments we found that A23187, at concentrations below 1.6  $\mu\text{M}$ , had no effect on the muscle fibre resting and action potentials. With cells loaded at higher ionophore concentrations (up to 15  $\mu\text{M}$ ) the resting potentials were slightly diminished and the action potentials showed reduced rates of rise and fall. Statistical analysis, however, indicated that these differences are of doubtful significance, in contrast with the marked effects observed in experiments utilising the divalent cation ionophore X537A (ref. 14).

All of the A23187 solutions used in our experiments caused some increase in m.e.p. frequency; typical values are given in Table 1. The small increase from 1.1 to 1.4 s<sup>-1</sup> at 0.56  $\mu\text{M}$  A23187 is not statistically significant, but the differences do become

significant at the higher ionophore concentrations. Often, with A23187 applied at high concentrations (bath or perfusion), prolonged high frequency bursts (showers) of m.e.ps were observed, followed by decreased frequencies below control levels.

The above findings indicated that A23187 functioned as an electroneutral calcium ionophore in the skeletal muscle preparations, since calcium ion influx triggers both quantal release of acetylcholine from nerve terminals<sup>15</sup> and activates the contractile mechanism in muscle fibres<sup>16</sup>. Further support for this conclusion was obtained when perfusion of 6  $\mu\text{M}$  A23187 solution ( $\text{Ca}^{2+}$ -free) failed to produce either retraction clots or increased m.e.p. frequencies in fibres bathed in Ringer solution in which the  $\text{Ca}^{2+}$  had been replaced with  $\text{Mg}^{2+}$ .

Desensitisation experiments were performed using constant current iontophoretic pulses of carbamylcholine<sup>17</sup>. The applied current pulses flowing through the iontophoretic micropipette and the corresponding evoked membrane potential changes were monitored continuously. Endplate regions of high sensitivity to the agonist were first located using single 5–10 ms duration iontophoretic pulses giving approximately 1 mV depolarisation responses, thus avoiding any preliminary desensitisation effects<sup>18</sup>. Trains of iontophoretic pulses ranging from 0.4 s duration at 1.0 Hz to 1.0 s at 0.5 Hz were then generated.

During delivery of the first few iontophoretic pulses, the evoked membrane potential changes produced by the applied carbamylcholine generally increased in amplitude over the

\*Ringer solution contains 1.8 mM  $\text{Ca}^{2+}$  all fibres below bathed in Ringer solution containing 3.6 mM  $\text{Ca}^{2+}$ .

†After the control period, the fibre was perfused with 2.4  $\mu\text{M}$  A23187 solution ( $\text{Ca}^{2+}$ -free ethanol–0.16%) for 1 to 2 min; recordings were then repeated 10 to 15 min after perfusion.

‡After the control period, 0.56  $\mu\text{M}$  A23187 (0.04% ethanol) was bath applied to the fibre and recordings were repeated in the presence of the ionophore after waiting 30 to 60 min.

§Maximum depolarisation pulse amplitude (see Fig. 1).

¶Final (steady-state) depolarisation pulse amplitude (see Fig. 1).

¶No desensitisation.

first few pulses to a maximum,  $\Delta V_{\max}$  then declined in amplitude to a final steady response  $\Delta V_f$  as illustrated in Fig. 1. The phenomenon of increasing  $\Delta V$  amplitudes which occurs with the first few iontophoretic pulses is not an artefact but represents a physiological potentiation phenomenon<sup>19,20</sup>. The decline in evoked potential amplitude which, occurred after the maximum response was obtained, indicated that desensitisation was in progress. The time  $\tau_1$  for these depolarisations to decline from  $\Delta V_{\max}$  to  $\frac{1}{2}(\Delta V_{\max} + \Delta V_f)$  was taken as a measure of the desensitisation rate. Comparisons of control and ionophore treated fibres were made only between recordings taken at the same postjunctional location on a given fibre because under control conditions there has been found to be a large variation in desensitisation rates amongst endplates from the same muscle<sup>18</sup>.

The results of these desensitisation experiments, presented in Table 2, demonstrated that very low concentrations of A23187 accelerated the desensitisation rate by 30% to 60%. For example, the desensitisation half time for fibre 1, which was 11.5 s in the control, decreased to 8.0 s after perfusion with 2.4  $\mu\text{M}$  A23187 solution. Apparently A23187 did not alter the sensitivity of the fibres to carbamylcholine, because following its application inconsequential random changes in the value of  $\Delta V_{\max}$  occurred. Direct measurement of endplate sensitivities, determined as membrane response in  $\text{mV nC}^{-1}$  of applied iontophoretic drug, confirmed this conclusion. Thus A23187 did not promote desensitisation by direct antagonistic interaction with the cholinergic receptors.

From the data we and others have obtained showing that A23187 carries calcium ions across excitable membranes, it could be concluded that the substantial acceleration of desensitisation by the ionophore was due to its action in increasing calcium ion influx both in the resting and the carbamylcholine activated postsynaptic membrane. We wondered what increase in intracellular calcium concentration would be produced by the action of A23187 alone. The concentrations of A23187 used in the desensitisation experiments were well below those at which retraction clots or changes in the electrical characteristics of the excitable membrane were produced. Thus if the minimal concentration of  $\text{Ca}^{2+}$  required to activate the contractile mechanism<sup>21</sup> is  $10^{-6}$  M then one might conclude that the  $[\text{Ca}^{2+}]_i$  in these ionophore loaded fibres was less than  $10^{-6}$  M before development of desensitisation by application of carbamylcholine.

Although the ionophore produced increase in  $[\text{Ca}^{2+}]_i$  seems too be small, its effect become evident during application of

desensitising iontophoretic pulses of carbamylcholine which further increase  $\text{Ca}^{2+}$  influx across the postjunctional membrane. We attempted to calculate the increase in  $[\text{Ca}^{2+}]_i$  resulting from the action of A23187 alone but the value obtained was clearly too high and we attributed this apparently erroneous result to the many questionable assumptions involved in the calculation.

In the above speculations it is tacitly assumed that the influxing  $\text{Ca}^{2+}$  ions are free to distribute themselves in the adjacent intracellular fluid. As suggested earlier<sup>6</sup>, however, the possibility exists that during production of receptor desensitisation influxing  $\text{Ca}^{2+}$  ions become bound to anionic sites on the interior surface of the postjunctional membrane and also accumulate in the intracellular fluid immediately adjacent to this membrane. In this model a relatively small amount of influxing  $\text{Ca}^{2+}$  could produce a substantial localised increase in calcium concentration. Such a localised increase in calcium would not necessarily cause a retraction clot because, as can be seen in electron micrographs, the intracellular region immediately adjacent to the postjunctional membrane does not contain contractile elements and in addition, some of the intracellular calcium would not be free.

The effect of the increase in  $[\text{Ca}^{2+}]_i$  produced by A23187 becomes evident during application of desensitising iontophoretic pulses of carbamylcholine to the postjunctional membrane which further increase  $\text{Ca}^{2+}$  influx. We suppose that  $\text{Ca}^{2+}$  ions exert some positive cooperative action in stabilising an inactive receptor state, or a closed ion channel conformation. Binding studies with purified acetylcholine receptor (AChR) have shown that ACh receptor has a fairly high affinity for  $\text{Ca}^{2+}$  and that  $\text{Ca}^{2+}$  influences the affinity of ACh receptor for cholinergic agonists<sup>22-24</sup>. If we assume that the agonist-receptor complex goes spontaneously through a series of active and then inactive states, a small localised increase in  $\text{Ca}^{2+}$  might maintain an ever increasing number of receptors in a complex but inactive state.

## Does ionophore A23187 mediate Na transport in the absence of divalent cations?

THE divalent cation-selective ionophore A23187 is known to form complexes with monovalent cations<sup>1</sup>, but it is not clear whether such complexes actually translocate across biological membranes. In the absence of Ca and Mg, the ionophore can transport K across the mitochondrial membrane in a manner reminiscent of the nigericin class of ionophores<sup>2</sup>. From spectrofluorometric and bulk organic phase partition data<sup>3</sup>, Pfeiffer and Lardy concluded that Na binds to the ionophore better than K ( $\text{Li} \gg \text{Na} > \text{K} \approx \text{O}$ ) and it is surprising that no observations of this Na form of the ionophore crossing biological membranes have been reported. We have used a recently developed method<sup>3</sup> designed to study the effect of intracellular Mg on the various ion fluxes mediated by the Na pump, and we report here that intact human red cells incubated in buffered isotonic NaCl media containing EDTA, no added divalent cations and the ionophore

**Fig. 1** Effect of the ionophore A23187 on the uptake of sodium by intact red cells at various Mg concentrations. Red cells from 2-d-old bank blood were washed in Tris-buffered isotonic saline and resuspended at a haematocrit of 10% in a medium initially containing NaCl 150 mM, Tris-HCl 10 mM (pH 7.7 at 37 °C), Tris-EGTA 0.01 mM, Tris-EDTA 2 mM and ouabain  $10^{-4}$  M. The suspension was divided into six equal parts and  $\text{MgCl}_2$  was added from a concentrated stock solution (0.8 M) to give the initial total concentrations reported here ( $[\text{Mg}]_0^{t=0}$ ). Values of  $[\text{Mg}]_0^{t=0}$  were (mM):  $\circ$ , 0;  $\bullet$ , 0.5;  $\triangle$ , 1.0;  $\blacktriangle$ , 1.5;  $\square$ , 2.1;  $\blacksquare$ , Control (no ionophore). At  $t = 0$ , 5  $\mu\text{l}$  of absolute ethanol containing 1 mg  $\text{ml}^{-1}$  of ionophore A23187 were added (arrow) per ml of suspension during vigorous magnetic stirring (at 37 °C). Samples of 1 ml were taken at the indicated times. The cells were centrifuged and washed three times with 40 volumes of ice-cold Tris-buffered choline chloride solution. Na and K were determined by flame photometry. Concentrations are expressed in mmol per 1 original cell volume. The initial concentration of K in the cells was  $89.8 \pm 1.4$  and the final concentration was between 87.5 and 88.6 in the controls and high-Mg conditions and between 81.6 and 84.5 at the lowest Mg concentrations.

**Table 1** Effect of A23187 on unidirectional fluxes of  $^{24}\text{Na}$  in the presence or absence of Mg in low-Na media

Medium	Ionophore A23187	$[\text{Mg}^{2+}]_i$ (M)	Na fluxes (mmol per 1 cells per h)	
			Influx	Efflux
K	—	$\sim 3.2 \times 10^{-4}$	$0.210 \pm 0.014$	$0.836 \pm 0.009$
Choline	—	$\sim 3.2 \times 10^{-4}$	$0.137 \pm 0.008$	$1.377 \pm 0.009$
K	+	$3.2 \times 10^{-4}$	$0.198 \pm 0.008$	$0.747 \pm 0.013$
Choline	+	$3.2 \times 10^{-4}$	$0.147 \pm 0.006$	$1.216 \pm 0.017$
K	+	$\sim 10^{-7}$	$0.290 \pm 0.006$	$1.330 \pm 0.047$
Choline	+	$\sim 10^{-7}$	$0.292 \pm 0.012$	$1.495 \pm 0.021$

Fresh, washed human red cells were incubated with or without  $^{24}\text{Na}$  for 4 h at 37 °C in a Tris-buffered medium containing NaCl 75 mM and KCl 75 mM. The cells were then washed and suspended at a haematocrit of about 10% in a medium containing NaCl 5 mM, Tris-Cl 10 mM, Tris-EGTA 0.01 mM, Tris-EDTA 2 mM, ouabain  $10^{-4}$  M and 145 mM of either KCl or choline chloride.  $\text{MgCl}_2$  2.1 mM was present in groups three and four of the table giving the final concentrations of internal  $\text{Mg}^{2+}$  as indicated.  $^{24}\text{Na}$  was added to the suspension of tracer-free cells to measure Na influx. Na fluxes were calculated by multiplying the internal (expressed per 1 of cell water for efflux) and external (for influx) Na concentrations by the respective rate constants of tracer movement (the influx rate constant was corrected for backflux).

A23187, gain Na and swell. This effect was not accompanied by any change in the K permeability and could be prevented or reversed by adding Mg or Ca to the medium. Thus, in certain conditions A23187 may indeed mediate Na transport.

The effect of the ionophore A23187 on the bulk and tracer ( $^{24}\text{Na}$ ) fluxes of Na was investigated in intact red cells suspended in 'Ca-free' media containing ouabain, in order to avoid both Ca-induced changes in K permeability<sup>4,5</sup> and variations in Na-pump rate that occur at different internal Mg concentrations (to be reported elsewhere; see also ref. 6). Figure 1 shows the effect of the ionophore on the Na content of cells suspended in isotonic Na media containing increasing Mg concentrations. The nominally Mg-free cells ( $[\text{Mg}]_i \approx 10^{-7}$  M) gained about 18 mmol of Na per 1 of cells in 1 h, a value about 10 times the Na gain in ionophore-free cells or in cells containing ionophore and normal Mg. The net Na influx is plotted as a function of  $[\text{Mg}^{2+}]_i$  in Fig. 2, showing half-maximum inhibition in the micromolar range. The increase in Na flux was fully reversed by physiological concentrations of internal Mg. Ca was also found to inhibit the Na influx in the presence of the ionophore but this effect was masked to some extent by a separate action of Ca on the Na influx. Ca tended to increase the Na influx compared with Ca-free controls even in the presence of high concentrations of Mg, and made it difficult to assess the precise extent to which Ca inhibited the ionophore-mediated influx.

In order to avoid large changes in ion composition and cell volume, the effect of the ionophore on the unidirectional ( $^{24}\text{Na}$ ) tracer fluxes was investigated in media containing 5 mM Na with either K or choline as the main extracellular cation. The results of one such experiment are reported in Table 1. Here again it can be seen that the ionophore increases the unidirectional Na fluxes only in the absence of Mg. At the same time, however, the K content of the ionophore-treated cells was the same as that of untreated controls in a similar medium. Na efflux is increased relatively more when K is the main external cation, while the effect on the influx of Na is relatively larger in the choline medium. This seems to result from an apparent effect of external K on the mechanism which is responsible for the asymmetry between Na efflux and Na influx in the presence of ouabain<sup>7</sup> and which had been variously attributed in the past to a second Na-pump<sup>8</sup>, to counter-transport of Na

Fig. 2 Net gain of sodium as a function of the intracellular concentration of free Mg in intact red cells in the presence of the ionophore A23187. The Na uptake of Fig. 1 is plotted as a function of the  $Mg^{2+}$  content of the cells calculated from the ionophore-induced equilibrium distribution of Mg as reported previously<sup>3</sup>.

with choline or  $Mg^{2+}$  or to co-transport of Na with  $K^{10,11}$ . The present results rule out symmetric carrier-mediated transport involving choline, K or Mg, as Na efflux is larger than Na influx in all conditions, whether in the presence or absence of choline, K, or Mg gradients. The persistence of the asymmetric Na fluxes even in 'Mg-free' cells also argues against ATP-fuelled transport associated with a Mg-dependent ATPase<sup>12</sup>.

In order to discriminate between a possible indirect

effect of the ionophore and ionophore-mediated Na flux, we measured net Na influx in cells that had been treated with the ionophore in the presence and absence of Mg and from which the ionophore had been washed away<sup>5,13</sup>. This was done to see whether 'Mg-free' cells with little or no ionophore left could still exhibit the increased Na permeability. The results (Table 2) showed that the 'Mg-free' cells did not have an increased Na permeability unless the ionophore was restored during the final incubation. All the available evidence suggests either that the ionophore can act on the membrane to produce a reversible and selective increase in Na permeability at low  $Mg^{2+}$  or  $Ca^{2+}$  concentrations, an interesting possibility which cannot be ruled out, or, more likely, that the ionophore itself mediates Na transport when the concentration of competing divalent cations is very low.

We thank the Wellcome Trust Foundation and the MRC for providing funds to V.L.L., the Lilly Research Centre for a gift of the ionophore A23187, A. M. Brown for helpful comments and Mrs Gray for technical assistance. P.F. is an MRC Scholar.

Table 2 Effect of ionophore removal on Na influx in the presence and absence of internal Mg

Pretreatment of the cells	Ionophore A23187 during final incubation	Presence of Mg during final incubation	Na influx (mmol per 1 cells per h)
Controls	—	—	$2.76 \pm 0.104$
	—	+	$1.60 \pm 0.154$
	+	—	$25.79 \pm 0.461$
	+	+	$3.48 \pm 0.259$
Treated with ionophore in the absence of Mg	—	—	$3.43 \pm 0.459$
	—	+	$3.92 \pm 0.382$
	+	—	$26.99 \pm 0.590$
	+	+	$3.80 \pm 0.446$
Treated with ionophore in the presence of Mg	—	—	$1.97 \pm 0.236$
	—	+	$2.13 \pm 0.346$
	+	—	$28.84 \pm 0.708$
	+	+	$2.90 \pm 0.273$

Cells were pretreated with A23187 in the presence and absence of 2.1 mM  $MgCl_2$  in a Tris-buffered isotonic choline chloride medium containing 5 mM NaCl. A low sodium medium was used to prevent changes in the intracellular Na concentration during the preincubation. 5  $\mu$ l of a 1 mg ml<sup>-1</sup> solution of the ionophore in absolute ethanol was added for each ml of the suspension. The haematocrit was about 10% and the pre-incubation was performed at 37 °C for 30 min. The ionophore was absent from the control group, otherwise conditions were identical. The cells were subsequently washed five times in a similar ice-cold solution and resuspended in a medium containing NaCl 150 mM; Tris-HCl 10 mM (pH 7.7 at 37 °C), Tris-EGTA 0.01 mM, Tris-EDTA 2 mM and ouabain 10<sup>-4</sup> M.  $MgCl_2$ , when present, was at 2.1 mM. <sup>24</sup>Na was added to the final incubation medium in order to measure Na influx. When the ionophore was absent, the 'Mg-free' cells did not gain Mg in the Mg-containing media.

## Lowering of hypertension by central saralasin in the absence of plasma renin

A ROLE for the renin-angiotensin system in the development or maintenance of increased blood pressure of spontaneously hypertensive (SH) rats has not been substantiated. These animals are considered the best model for human essential hypertension. Although there have been reports of unusually high concentrations of renin in the plasma of young SH rats<sup>2</sup>, their pathophysiological relevance has been questioned<sup>3</sup> and, as we report here, high blood pressure is maintained even after nephrectomy. But angiotensin from the brain isorenin-angiotensin system (Iso-RAS) could be involved<sup>4,5</sup>. All the components of that system have been identified in brain tissue, including the enzyme iso-renin<sup>4-6</sup>, the substrate, angiotensinogen<sup>7</sup>, angiotensin I and converting enzyme<sup>6,8</sup> which hydrolyses angiotensin I to form the biologically active octapeptide angiotensin II. Angiotensin II is also present in brain tissue<sup>6</sup>. When it is injected intraventricularly into the brain angiotensin II produces a prolonged increase in blood pressure<sup>9</sup>. Therefore, if angiotensin II concentrations are increased in the brains of SH rats they could be involved in the hypertensive state independently of angiotensin levels from renal origin in plasma. Using the competitive antagonist Sar-1-Ala-8-angiotensin II (saralasin acetate, P113, Norwich Pharmacal) in SH and nephrectomised SH rats, we have confirmed this possibility.

Twenty-one SH stroke-prone (SH-SP) rats weighing 220-330 g and 10 age matched Wistar Kyoto control rats (WKY) were anaesthetised by ether, and a 28-gauge stainless steel cannula was implanted stereotactically into the right lateral ventricle. Rats were allowed 3-10 d for recovery and were

again anaesthetised with ether. A femoral vein catheter (polyethylene No. 10 tubing, Clay Adams, USA) and a femoral artery catheter (polyethylene No. 10 connected to No. 50 tubing) were inserted, ligatured and brought under the skin to exit through the scruff of the neck. A 1-ml blood sample was taken from the arterial catheter for plasma renin assay and simultaneously replaced by 1 ml isotonic saline through the venous catheter. Rats were left awake, freely moving in a wooden box during testing and recording. Blood pressure was recorded by a Statham transducer P 23 b and Hellige pre-amplifiers on to a Brush 220 polygraph. Testing began 90–120 min after blood pressure had become stable.

Ten SH-SP and six WKY male and female rats, all 4-months-old, were tested with intravenous and intraventricular doses of saralasin. Eleven SH-SP rats and four WKY rats (all females, 8-months-old) were nephrectomised and tested. Bilateral nephrectomy was carried out under ether anaesthesia and rats were tested 15–20 h later. Blood samples for plasma renin assays were also taken 15 h after nephrectomy.

To test the potency of the preparation each rat was tested initially with 100 ng angiotensin II intravenously and intraventricularly. After 1 h, saralasin was infused intravenously in cumulative doses of 0.1, 1.0, 10.0 and 100  $\mu\text{g}$  per kg per min for 15 min at each dose. Sixty min after the infusion test a bolus injection of 50  $\mu\text{g}$  saralasin was given intravenously. After 2–3 h recovery when blood pressure was stable, testing began with intraventricular injections of 5, 10 and 20  $\mu\text{g}$  saralasin in 0.5, 1.0 and 2.0- $\mu\text{l}$  volumes, respectively. The order of testing was randomised and there was full recovery of the original blood pressure between tests. Saralasin was dissolved in artificial cerebrospinal fluid and control injections of 2  $\mu\text{l}$  of this vehicle were also given.

The results are illustrated in Figs 1 and 2. The mean arterial blood pressure of SH-SP rats was  $181.3 \pm 9.2$  mmHg. Intraventricular saralasin lowered blood pressure in a dose-response relationship in every rat tested ( $n = 14$ ) (Fig. 1). In the 4-month-old rats 5  $\mu\text{g}$  saralasin produced a decrease of  $2.5 \pm 2.3$  mmHg. The 10- $\mu\text{g}$  dose lowered blood pressure by  $7.8 \pm 1.2$  mmHg and the 20- $\mu\text{g}$  dose by  $12.5 \pm 1.9$  mmHg ( $P < 0.01$  compared with controls by the *t*-test). A 20- $\mu\text{g}$  dose of saralasin lowered blood pressure in the 8-month-old rats by  $8.3 \pm 1.4$  mmHg ( $P < 0.01$  compared with controls). The decrease began in each case within 1 min of injection and reached a maximum by

**Fig. 1** Changes in mean arterial blood pressure ( $\Delta$  BP in mmHg) after injections of the angiotensin blocker saralasin into the cerebral ventricles of spontaneously hypertensive rats of the stroke-prone strain and into the cerebral ventricles of normotensive Wistar Kyoto control rats. Doses of intraventricular saralasin are indicated below. Pre-NX: rats tested before and in the same animals 16 h after bilateral nephrectomy (Post-NX). Dotted columns, 4-month-old ( $\bar{X} \pm \text{s.e.m.}$ ); open columns, age-matched controls; striped columns, 8-month-old.

**Fig. 2** The effect of intravenous saralasin infusions in cumulative doses on the mean arterial blood pressure (BP) of spontaneously hypertensive rats of the stroke-prone strain.

5–7 min. There was recovery back to the original blood pressure within 15–30 min. WKY rats matched for age showed no response to intraventricular saralasin (Fig. 1). When saralasin was given intravenously the two smallest doses caused increase of blood pressure in SH ( $n = 6$ ) and control rats ( $n = 6$ ) ( $P < 0.05$ ) (Fig. 2). Bolus injection of 50  $\mu\text{g}$  saralasin consistently produced an even more marked increase in blood pressure in both SH ( $23.4 \pm 2.5$  mmHg) and control rats ( $35.3 \pm 2.6$  mmHg) (Fig. 2).

To investigate whether circulating plasma angiotensin II of renal origin was involved in the central effect of saralasin we repeated the test in nephrectomised rats. In nephrectomised SH-SP rats the mean lowering of blood pressure by 20  $\mu\text{g}$  saralasin given intraventricularly was  $14.1 \pm 3.8$  mmHg. Intraventricular saralasin had no effect on blood pressure in nephrectomised control rats. Plasma renin activity in these rats was  $0.5 \pm 0.1$  ng angiotensin I  $\text{ml}^{-1} \text{h}^{-1}$ , which is close to detection limits of the assay and lower as compared with the control levels in SH rats of  $5.7 \pm 0.8$  ng angiotensin I  $\text{ml}^{-1} \text{h}^{-1}$ . Nephrectomy did not affect the blood pressure of control or experimental rats. The mean arterial pressure before nephrectomy was  $178.3 \pm 6.2$  mmHg and after nephrectomy it was  $178.0 \pm 6.3$  mmHg.

The response to angiotensin II in SH rats seemed to be greater than in WKY rats, as recently confirmed<sup>15</sup>.

These data implicate angiotensin in the central blood pressure regulation of SH rats. Although the effect was comparatively small, the consistency with which intraventricular saralasin lowered the blood pressure may reflect further factors which tend to maintain blood pressure in these rats. The effect is not readily obtained when blood pressure is lower<sup>16</sup>, nor was it obtained in normotensive control rats. The results also demonstrate that in the absence of peripheral plasma renin after nephrectomy, the blood pressure of SH rats is still increased.

The lowering of blood pressure by central saralasin in the absence of peripheral renin-angiotensin is evidence for a role of the brain iso-renin-angiotensin system in the maintenance of high blood pressure in SH-SP rats. Since its discovery<sup>1,5</sup>, several lines of evidence have suggested that the system has a physiological function. Electrophysiological evidence and recent biochemical binding studies have demonstrated angiotensin receptors in the brain<sup>10–13</sup>. Saralasin slowed the rate of firing of cells responsive to angiotensin<sup>10</sup>. This has been

interpreted to mean that the spontaneous rate was normally maintained at high rates by endogenous angiotensin. A reduction of blood pressure by central infusions or injections of angiotensin antagonists has been reported in other strains of SH rats (New Zealand and Okamoto strains)<sup>14-18</sup>, but negative findings have also been claimed<sup>19</sup>. Without nephrectomy these results were only circumstantial evidence for an action of extrarenal angiotensin. With the data reported here we conclude that extrarenal angiotensin acts on the brain receptors and contributes to the high blood pressure in SH-SP rats. In view of the growing support for the presence of locally formed brain angiotensin<sup>20</sup>, the brain iso-renin system is a likely extrarenal source.

We thank Dr A. Castellion, Norwich Pharmacal and Dr Völger, Röhm Pharma for the gift of saralasin. This work was supported by the Deutsche Forschungsgemeinschaft (SFB 90) and Humboldt Fellowship to M.I.P.

## Thyroid-stimulating autoantibody production *in vitro*

GRAVES' disease is an autoimmune disorder in which hyperthyroidism is associated with the presence of thyroid-stimulating autoantibodies<sup>1</sup>. Recent work suggests that these antibodies, collectively termed TSAb, are antibodies to the thyrotrophin (TSH) receptor which stimulate the thyroid by binding to the receptor and activating adenylate cyclase<sup>1-5</sup>. Synthesis of the autoantibody *in vivo* may result from defects in both the thyroid and the immune system. In the case of the thyroid, this may be an aberration in the synthesis or shedding of plasma membrane components related to the TSH receptor. In the case of the immune system, a current view is that autoantibody formation is the result of a suppressor T cell defect<sup>6</sup>. An *in vitro* model of TSAb synthesis would permit an analysis of the role of the thyroid and the immune system in the events leading to thyroid-stimulating antibody production. Attempts have been made to study TSAb production in short-term cultures of peripheral blood lymphocytes from Graves' patients.

**Fig. 1** Kinetics of IgG production by peripheral blood lymphocytes. Lymphocytes were separated on a Ficoll-Hypaque gradient<sup>19</sup> and washed three times; the yield from heparinised blood averaged 80%. The cells were incubated at  $1.0-1.5 \times 10^7$  per ml in 1 ml aliquots in Marbrook flasks with an outer reservoir of 25 ml. The culture medium was RPMI 1640 buffered with  $\text{NaHCO}_3$  and supplemented with L-glutamine (2 mM), penicillin ( $50 \text{ U ml}^{-1}$ ), streptomycin ( $50 \text{ } \mu\text{g ml}^{-1}$ ) and 10% heat inactivated foetal calf serum (Flow Laboratories, Lot 428136). Lymphocytes were incubated at  $37^\circ\text{C}$  in 5%  $\text{CO}_2$  in air for intervals of up to 28 d and collected as follows: the cell suspensions were removed from the Marbrook flasks, centrifuged and the culture supernatants separated from the cell pellets. Soluble material was extracted from the cell pellets by freezing, thawing and homogenising; the homogenates were centrifuged ( $100,000g$  for 30 min) and the supernatants (termed the soluble cell extract) collected. IgG was measured in the culture supernatants and soluble cell extracts by a solid phase radioimmunoassay<sup>20</sup>. Each kinetic curve is derived from the lymphocytes separated from 100 ml of blood from a single donor; each point is the mean of duplicate or triplicate cultures. Results are expressed as  $\mu\text{g}$  IgG produced per  $10^7$  cells initially added to each flask. ● and ○, IgG in the supernatants from cultures stimulated with PWM (Gibco,  $10 \text{ } \mu\text{l ml}^{-1}$ ); ▲ and △, IgG in cell extracts of cultures stimulated with PWM; ■ and □, IgG in the supernatants of cultures without mitogen.

These studies, however, did not use optimal conditions for immunoglobulin production and the levels of TSAb reported were close to the limits of detectability of the imprecise assay methods used<sup>7-11</sup>. In the study described here we have used the optimal conditions for culturing lymphocytes provided by Marbrook flasks<sup>12</sup> in conjunction with two new sensitive and precise methods for detecting TSAb—the radio-receptor<sup>13</sup> and cytochemical assays<sup>14,15</sup>. With this system we have readily been able to detect TSAb production in cultures of Graves' lymphocytes.

Thyroid-stimulating antibodies are always associated with the IgG fraction of serum. Therefore in preliminary experiments a study of the kinetics of IgG production *in vitro* was made using peripheral blood lymphocytes from normal donors. Lymphocytes were cultured for up to 28 d in medium alone or medium containing pokeweed mitogen (PWM) and the IgG in the culture supernatants measured by solid phase radioimmunoassay. Also, the amount of immunoglobulin remaining in the cells was determined. Some representative experiments are shown in Fig. 1. After 10 d of culture in the presence of PWM the medium contained about  $100 \text{ } \mu\text{g}$  of IgG per  $10^7$  cells and this was increased to  $200 \text{ } \mu\text{g}$  after 21 d. The cell extracts contained far less IgG. In the absence of PWM, only small

**Table 1** TSAb activity in supernatants from lymphocyte cultures measured by cytochemical assay

Culture conditions	Patient	IgG dose ( $\mu$ g)	% Stimulation	Donor	IgG dose ( $\mu$ g)	% Stimulation
Membranes + PWM	Bu	0.64	35.7	Bo	0.22	0.4
PWM	Ca	0.88	28.6	Pe	0.60	2.9
PWM	Gl	0.82	38.0	Sm	0.56	2.2

Lymphocytes were incubated with PWM, alone or after an initial 24-h period with thyroid membranes. Immunoglobulins in the culture supernatants and medium alone were precipitated using ammonium sulphate, dialysed exhaustively against isotonic saline and assayed in the section assay for thyroid stimulators<sup>21</sup>. The results are expressed as % stimulation of the absorbance (*A*) over control values (medium only) calculated from the formula:

$$[(A_{\text{test sample}} - A_{\text{control}})/A_{\text{control}}] \times 100$$

Each absorbance value is the mean of 10 measurements per slide on duplicate slides. The amount of IgG used for each assay is given. All three Graves' patients studied had high levels of serum TSAb activity.

amounts of IgG were detected in the medium and cell extracts. The ability of PWM to stimulate immunoglobulin production in human lymphocyte cultures is well known<sup>16,17</sup>. On the basis of these experiments it was decided to investigate thyroid-stimulating antibody production by culturing Graves' lymphocytes with PWM and assaying the culture supernatants for TSAb after 14 d. This time interval was chosen so as to provide near-maximal amounts of IgG while reducing the risk of infection which is a problem with long-term cultures.

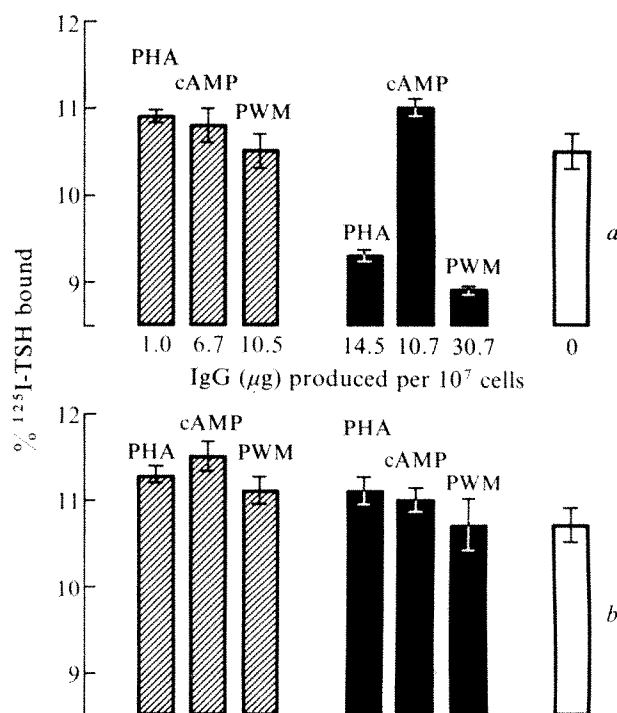

Table 1 shows the measurement of TSAb activity by cytochemical assay in the immunoglobulin fraction of the culture supernatants from Graves' and normal peripheral blood lymphocytes. The assay depends on detecting TSAb- (or TSH)-induced increases in the permeability of thyroid cell lysosomes. These increases are monitored by using a chromogenic substrate (leucyl- $\beta$ -naphthylamide) for the lysosomal enzyme naphthylamidase and the intensity of the resulting intracellular colour is quantitated by scanning and integrating microdensitometry. The supernatants from all three Graves' lymphocyte cultures produced an increase in absorbance of 30–40% over control (medium only) whereas the responses elicited by supernatants from cultures of normal lymphocytes were less than 3%. This study, in which the assay of the supernatants from cultures of normal and Graves' lymphocytes was carried out 'blind', provided good evidence that TSAb was produced by the cultured Graves' lymphocytes.

Confirmation of the presence of TSAb in Graves' lymphocyte cultures was provided by studies with the radioreceptor assay for thyroid-stimulating antibodies which depends on the ability of TSAb to inhibit the binding of labelled TSH to thyroid membranes<sup>1,3-5,13</sup>. In these experiments, lymphocytes were cultured with antigen (in the form of thyroid membranes) for 24 h. One-third of the cells were also treated with dibutyryl cyclic AMP during this period since there is evidence from experiments with mice that cyclic AMP administered with antigen *in vivo* and *in vitro* results in higher numbers of antibody-forming cells<sup>18</sup>. After 24 h, the cells were washed and re-suspended in medium alone (for cyclic AMP-treated cells) or medium plus PWM or phytohaemagglutinin (PHA). The supernatants from 14-d cultures were assayed for IgG and the immunoglobulins of the supernatants monitored for TSAb activity in the receptor assay. A significant inhibition of labelled TSH binding to thyroid membranes was observed with supernatants from Graves' lymphocytes cultured with PHA (Student's *t* = 24.5, *P* < 0.001) and PWM (*t* = 7.1, *P* < 0.01) and this indicated the presence of TSAb (Fig. 2a). The specificity of the effect of the cultures in the receptor assay was demonstrated by the experiment shown in Fig. 2b in which supernatants from the same cultures were pre-incubated with thyroid membranes before assay; the TSAb activity originally present in the PHA and PWM cultures was absorbed out.

These observations indicated that peripheral blood lymphocytes from patients with Graves' disease are capable of making thyroid-stimulating autoantibodies when cultured under the conditions provided by Marbrook flasks<sup>22</sup>. It should now be possible to use the combination of the Marbrook culture

system with the precise and sensitive cytochemical and radio-receptor assays to investigate the events leading to TSAb production. Similarly, autoantibody production in other human autoimmune diseases could be studied using this approach.

We thank Drs Chayen and Bitensky, from the Kennedy Institute of Rheumatology, for considerable help with the cytochemical bioassay. We also thank Drs J. G. Pierce and J. Fawcett and the Armour Pharmaceutical Company for gifts of TSH, Professor J. Owen, Professor A. L. Latner, Professor

**Fig. 2** TSAb activity in supernatants of lymphocyte cultures measured by radioreceptor assay<sup>13</sup>. Lymphocytes were incubated with thyroid membranes (35  $\mu$ g protein ml<sup>-1</sup>) for 24 h, washed and then cultured with PHA (Wellcome 10  $\mu$ l ml<sup>-1</sup>), PWM (10  $\mu$ l ml<sup>-1</sup>) or medium only for 14 d; cells receiving medium only had been stimulated with dibutyryl cyclic AMP (cAMP, 0.4 mM) during the 24 h incubation with membranes. IgG was measured in the culture medium and the amount produced per 10<sup>7</sup> cells is shown. Immunoglobulins were precipitated from the culture supernatants with ammonium sulphate, dialysed exhaustively against 50 mM NaCl, 10 mM Tris-HCl (pH 7.4) and assayed in the radioreceptor assay. The figure shows the effect of the immunoglobulins on <sup>125</sup>I-TSH binding to thyroid membranes. *a*, Immunoglobulins assayed directly. *b*, Immunoglobulins pre-incubated with human thyroid membranes. All values are the means of triplicate  $\pm$  s.e.m. Data are given for a Graves' patient (solid bars), a normal donor (cross-hatched bars) and culture medium alone (open bars). The same number of cells were cultured from the Graves' patient and the normal donor. The Graves' patient studied in this experiment had particularly high levels of serum TSAb; 1  $\mu$ g of purified serum IgG was readily detectable in the receptor assay.

I. M. Roitt, Drs J. North, T. Platts-Mills, P. Lydyard and N. Wilcox for useful discussion and Mrs Alison Scaife for technical assistance. ## Relaxin has conformational homology with insulin

RELAXIN, a polypeptide hormone synthesised and stored in the corpus luteum, is responsible for the dilation of the symphysis pubis in most mammals before parturition. Porcine relaxin (molecular weight ~5,600) consists of one A chain and one B chain linked by disulphide bonds. The amino acid sequence of the two chains is consistent with interchain and intrachain disulphide crosslinks of the same disposition as those of insulin<sup>1,2</sup>. Although only five further residues are identical to those in equivalent positions of porcine insulin, the model presented here shows that relaxin may have a tertiary structure closely resembling that of

insulin. The residues of the hydrophobic core of relaxin differ from those of insulin but are close packed and occupy the same volume.

Figure 1 shows the sequence of porcine relaxin as determined by Schwabe *et al.*<sup>1,2</sup> aligned with the sequence of porcine insulin according to the positions of the cystines (for reviews see refs 3, 4). In this paper the insulin numbering scheme has been applied to the relaxin sequence to facilitate comparison of the equivalent residues in the two molecules. Some relaxin molecules apparently have additional residues, possibly serine and arginine at the C-terminus of the B chain<sup>2</sup>. This may, by analogy with insulin, be a consequence of there being a precursor, prorelaxin; these derivatives may be intermediates in the conversion process. A further sequence analysis of a porcine relaxin by Niall and co-workers<sup>5</sup> shows that there may be some heterogeneity in relaxin. Since these differences seem to be limited to residues at the B-chain termini located on the outside of the model presented here, they could be accommodated without affecting the relaxin tertiary structure that we describe.

We have explored a possible three-dimensional structural homology of insulin and relaxin in the following way. A model was built first of the main chain A1-A20 and B6-B21, in which the interchain and intrachain disulphide bridges occupied equivalent three-dimensional positions to those reported for insulin, and other amino acid residues shown to be equivalent in the sequence alignment of Fig. 1 were given the same main chain conformation. This was made possible by the presence of glycines at B8 and B20 in relaxin as in insulin, in which positions an amino acid with a side chain would not be allowed as a consequence of the positive  $\psi$  angles. The side chains of B6, B11, B12, B14, B15, B18, A2 and A16 which contribute to the hydrophobic core of insulin were then built into the framework provided by the main chain and cystine disulphides. These are all hydrophobic in relaxin and are easily accommodated to give a close packed core. B11 and B12 are conserved as in all insulins. Of particular interest is the complementary nature of many of the sequence differences. For example, in insulin B6 Leu and B14 Ala are in close juxtaposition; in relaxin their respective positions are reversed: B6 Ala and B14 Leu. In a similar way A2 Ile and A16 Leu of insulin are A2 Leu and A16 Ile in relaxin. These pairs of side chains point towards the centre of the core from opposite sides. The close-packed occupancy of the core is thus maintained. The B15 Trp of relaxin is beautifully accommodated almost completely buried in the core with no relative changes of the positions of the A and B chains. The proposed main chain conformation of relaxin is shown in Fig. 2 and a stereoview of the three-dimensional structure is shown in Fig. 3.

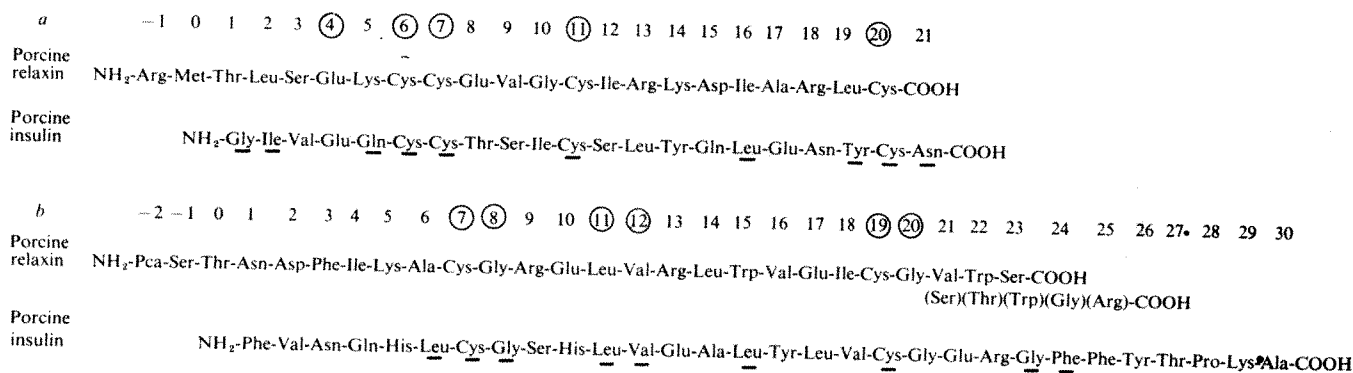

Fig. 1 Sequences of porcine relaxin<sup>1,2</sup> and insulin arranged to give alignment of the cystines. There may be further Ser and Arg residues at B24 and B25 in some relaxin molecules<sup>2</sup> and an independent sequence determination<sup>5</sup> indicates possible heterogeneity at B-2, B21, B22 and B23 (the sequence differences are given in parentheses). The numbers of residues identical in porcine insulin and relaxin are circled and residues invariant in all known insulins are underlined.

**Fig. 2** Proposed conformation of the relaxin main chain indicated by  $\alpha$  carbon positions ( $\circ$ ) and joined by virtual bonds. The residue numbers are those shown in Table 1 to facilitate comparison with insulin. The molecule is viewed from a position equivalent to right angles to the three-fold axis and into the face involved in dimerisation of the insulin hexamer (see Fig. 10 of ref. 3). In insulin the B chain continues from B23 to a position close to A2 partly covering the A chain residues as viewed here.

Having established the feasibility of an insulin-like fold for relaxin we then proceeded to add surface residues including the chains B6–B22 and A1–A20. This naturally led to the suggestion of many ion pairs in particular A5 Lys and A15 Asp of relaxin, which are A5 Gln and B15 Gln in insulin. Further possible relaxin ion pairs are A8 Glu and B5 Lys, B13 Arg and B17 Glu.

Residue A19 is Tyr in insulin and Leu in relaxin. This change is easily accommodated in the model and may be related to the extra residues at the A-chain N terminus of

relaxin which are most probably covering A19 so that A0 Met is in contact with Leu, leading to a further ion pair A–1 Arg to the B-chain C terminus. In a similar way the extra residues at the B-chain N terminus are easily accommodated. When residue B3 Phe was allowed to lie against the residues of the hydrophobic core, the chain could be further extended to fold over A12, a position which is Ile in relaxin although always hydrophilic in insulins. But, the conformations of the B-chain N terminal residues may be flexible in relaxin as they are in insulin, and it is possible that they contribute little to the stability of the insulin-like core. The absence of a residue at A21 might be expected to destabilise the insulin-like tertiary structure, but would not prevent its existence.

Although of less consequence for the tertiary structure of relaxin, the positioning of the residues at the B-chain C terminus must await clarification of this part of the primary structure. If the polypeptide chain has either of the reported sequences<sup>2,3</sup>, it can be folded back on to the hydrophobic core. The tryptophan probably contributes towards stabilising the tertiary structure. This residue may be placed so that it partially compensates for the lack of residues in relaxin equivalent to B24 Phe and B26 Tyr of insulin. Thus the tertiary structure would be expected to be more stable than that of desoctapeptide insulin (B23–B30 deleted) which has a tertiary structure rather different from that of native insulin. Residue A3 in our model of relaxin—a serine residue—occurs on the surface of the molecule whereas in insulin this residue is usually a valine and is close to the B-chain C terminus.

The uncertainty in the C-terminal B-chain sequence may be due to the existence of two variants of relaxin suggesting that this portion of the molecule makes only a limited, contribution, if any, to the biological activity. Thus, the tryptophan residue known to be inessential<sup>6</sup> is most likely the one located in the C-terminal tail of the relaxin B chain. Our model predicts that the remaining tryptophan B15 which is buried cannot be oxidised in native relaxin without loss of tertiary structure and probably therefore biological activity. The relative mobility of the C-terminal peptide of the B-chain may be deduced from the fact that carboxypeptidase A digestion of native relaxin readily releases Ser, Trp, Val, and somewhat more slowly, Gly.

The absence of histidine at B10 implies that relaxin will not bind zinc ions to give a hexamer in the same way as insulin, although the B10 Glu of relaxin may bind other metal ions such as calcium. But, the association of the protomers would also be hindered by the change of the C-terminus of the relaxin B-chain and the presence of charged groups at B17 and A13 in relaxin which are usually hydrophobic in insulin. The equivalent groups in

**Fig. 3** A stereo view of the relaxin model from approximately the same direction as Fig. 2. All side-chain residues are included with the exception of those of B21, B22 and B23. The tryptophan (B15) is seen centrally end on and partially buried in the hydrophobic core. The drawing is taken from coordinates measured from the model and constrained towards the known geometry of amino acids using the method described in ref. 9.

insulin are involved in protomer-protomer interactions in the zinc insulin hexamer.

The differences between residues at A1 and A19 and the deletions at the two chain termini make it unlikely that relaxin will bind insulin receptors, since modification or deletion of these residues in insulin leads to considerable loss of affinity for the receptor and a decrease of biological activity<sup>3,7</sup>.

Relaxin in its highly purified form requires an adjuvant such as beeswax or benzopurpurin 4- $\beta$  for enhancement of biological activity. This may well be due to interaction of the diazo dye, for example, with the hydrophobic residues, particularly tryptophan B22 and subsequent stabilisation of the structure and protection from proteolytic attack. The induction of a strong Cotton effect at 520 nm indicates that the dye molecules bind relaxin strongly and specifically (data not shown).

The existence of a molecule with the sequence of relaxin and an insulin-like tertiary structure may be explained by gene duplication of primitive insulin-like molecules followed by accepted mutations leading to radical changes in sequence<sup>8</sup>. If this is so, the nature of the complementary changes in the hydrophobic core implies evolution through a less easily folded state possibly implying a period without selective pressure on the duplicated gene.

We thank Mr D. Richardson and Dr P. Pauling of University College, London, and Mr T. Sewell and Mr J. Jenkins for assistance with computer graphics, Dr J. L. Finney and Mr J. D. Nicholas for use of their coordinate measuring device, and Miss S. Kennett for assistance with photography of the model. T.L.B. and S.B. are grateful to the SRC for support.

*Note added in proof:* An independent model building study using computer graphics has also concluded that relaxin has an insulin-like conformation (N. Isaacs *et al.*, manuscript in preparation).

## Nucleosome structure controls rates of excision repair in DNA of human cells

EUKARYOTIC chromatin is now considered to be composed of structural units, nucleosomes (nu bodies), which consist of four pairs of histones around which DNA is coiled<sup>1-3</sup>. Approximately 200 base pairs of DNA are associated with each nucleosome, 140 base pairs are wrapped around each and a variable length of approximately 40 base pairs lies between<sup>1-3</sup>. The DNA wrapped around each nucleosome is less easily digested by micrococcal nuclease than the DNA between them, and brief periods of incubation with the enzyme allow isolation of nucleosomes

**Fig. 1** Repair replication in confluent human fibroblasts. Cultures were incubated in the presence of BUdr  $10^{-5}$  M and FUdr  $2 \times 10^{-6}$  M for 1 h, irradiated with  $13 \text{ J m}^{-2}$  ultraviolet light and labelled for 2 h in BUdr  $10^{-5}$  M,  $^3\text{H}$ -Tdr  $10 \mu\text{Ci ml}^{-1}$  (64 Ci  $\text{mmol}^{-1}$ ), FUdr  $2 \times 10^{-6}$  M, hydroxyurea  $2 \times 10^{-3}$  M; the DNA was isolated and sedimented in alkaline caesium chloride gradients<sup>10,11</sup>. The exclusive location of  $^3\text{H}$  label at normal density (coincident with the absorbance peak) indicates that the  $^3\text{H}$  has been incorporated by repair replication. Broken line,  $A_{260}$ ;  $\circ$ , controls;  $\bullet$ , irradiation with  $13 \text{ J m}^{-2}$  ultraviolet. Radioactivity profiles were normalised to the same amount of DNA per gradient.

as discrete particles<sup>2</sup>. The structural organisation of mammalian DNA into nucleosomes, and higher degrees of order in the packing of strings of nucleosomes into chromosomal fibres has been shown to play a major part in the control of DNA replication<sup>4,5</sup>, and transcription<sup>6</sup>. Previous studies have indicated that the accessibility of damage in DNA to repair enzymes is restricted by chromatin proteins<sup>7,8</sup> and it is therefore likely that the repair of damaged sites in DNA is also controlled by some features of nucleosome structure and packing<sup>9</sup>. In the study described here I have measured the rates of degradation of repaired regions in mammalian DNA by micrococcal nuclease; the results suggest that the first sites of ultraviolet light-induced damage to be repaired are those in the DNA between nucleosomes and that there is little rearrangement of nucleosomes along the DNA during repair.

Human fibroblast cultures (strain E11) were established from foreskin and grown in Eagle's minimal essential medium with 10% foetal calf serum. Cultures for experiments were grown in  $0.01 \mu\text{Ci ml}^{-1}$ ,  $56.4 \text{ mCi mmol}^{-1}$   $^{14}\text{C}$ -thymidine ( $^{14}\text{C}$ -Tdr) in 90-mm Petri dishes until confluent and mitotic figures no longer detectable. Cultures were then rinsed and grown for 24 h in unlabelled medium before being once irradiated with  $13 \text{ J m}^{-2}$  ultraviolet light (254 nm, at a dose rate of  $1.3 \text{ J m}^{-2} \text{ s}^{-1}$ ). They were then labelled with  $^3\text{H}$ -Tdr ( $10 \mu\text{Ci ml}^{-1}$ ,  $64 \text{ Ci mmol}^{-1}$ ), hydroxyurea ( $5 \times 10^{-3}$  M), and fluorodeoxyuridine (FUdr,  $2 \times 10^{-6}$  M) for 10 min to 4.5 h. For most experiments cells were collected immediately but some were allowed to grow in  $5 \times 10^{-4}$  M Tdr and  $5 \times 10^{-5}$  M deoxycytidine for several hours before collection.

Confluent cultures of primary fibroblasts perform negligible amounts of semiconservative DNA replication, and all of the radioactivity incorporated into DNA in the presence of hydroxyurea after ultraviolet irradiation consists of repair replication (Fig. 1). Therefore, in cultures allowed to reach confluency in  $^{14}\text{C}$ -Tdr, irradiated with ultraviolet light and labelled with  $^3\text{H}$ -Tdr, the  $^{14}\text{C}$  activity is uniformly distributed throughout the DNA but the  $^3\text{H}$  activity is confined to the short patches which are involved in repair of ultraviolet damage in DNA<sup>10,11</sup>.

Repaired regions in cells that had incorporated  $^3\text{H}$ -Tdr immediately after ultraviolet irradiation were more rapidly digested by nuclease action than was  $^{14}\text{C}$ -Tdr-labelled DNA (Fig. 2, Table 1). When cells that had incorporated  $^3\text{H}$ -Tdr into repaired DNA immediately after irradiation had grown for 5 h, the  $^3\text{H}$  label was digested to a similar extent to that in cells collected earlier (Fig. 2, Table 1). When cells were labelled for longer periods the proportion of  $^3\text{H}$  activity that was rapidly digested decreased (Fig. 2, Table 1).

These results show that the rate at which nuclease degrades  $^3\text{H}$ -labelled DNA in repaired regions is different from that at which  $^{14}\text{C}$  uniformly labelled DNA is degraded. To a first approximation, the degradation kinetics can be analysed in terms of two exponential components (Fig. 2): an initial rapid component which is present in decreasing proportion as the labelling time increases, and a slow component which has approximately the same slope at all labelling times (Fig. 2, Table 1). The simplest interpretation of these results is that the rapid component represents degradation of the DNA between nucleosomes, and the slow component represents degradation of DNA closely associated with nucleosomes. This interpretation is strengthened by observation that the DNA after 5 min digestion with nuclease in essentially the same conditions in this laboratory is in one or more multiples of approximately 200 nucleotide pair lengths (B. Young, unpublished). The results indicate therefore, that at short times after irradiation the repaired regions are predominantly between nucleosomes, but after longer times all regions of DNA contain repaired regions.

There are two possible reasons for the change in the distribution of  $^3\text{H}$  label in repaired regions with increasing labelling times. One is that only internucleosome DNA is repaired and that there is a redistribution of nucleosomes along the DNA which tends to randomise the label. The other is that internucleosome DNA is more accessible to repair enzymes and is repaired more rapidly than DNA on the nucleosomes. Because the inter-nucleosome DNA and hence the ultraviolet-induced photoproducts in this DNA are a minor fraction of the whole DNA and a minor fraction of the total repair replication is completed in the first hour after irradiation (Table 1), faster repair in these regions will result in earlier completion of repair; at longer times repair on nucleosomes would predominate. The first possibility is eliminated, however, by the pulse-chase experiments. Growing cells for 5 h after a 30-min pulse of  $^3\text{H}$ -Tdr immediately following irradiation produced a  $^3\text{H}$  distribution that was similar to that obtained from similarly labelled cells collected earlier (Table 1). Cells that had been labelled for only 10 min, however, had a  $^3\text{H}$  distribution in which the rapidly digested component decreased from 58% to 39%. These observations at 10 and 30 min of labelling indicate that the distribution of DNA between and on nucleosomes changes little during 5 h of growth. The slight change observed in the 10-min labelled sample could actually be due to variability

**Fig. 2** Percentage of  $^{14}\text{C}$ - or  $^3\text{H}$ -labelled DNA in nuclei remaining undigested by micrococcal nuclease after various times of incubation at  $37^\circ\text{C}$ . After cultures were labelled and irradiated as described in the text, cells were collected by rinsing once in physiological buffer, trypsin treatment for 2 min at  $37^\circ\text{C}$  and the suspension was centrifuged at  $1,800g$  for 1 min. Cells were resuspended in ice-cold hypotonic buffer (RSB,  $0.0015\text{ M MgCl}_2$ ,  $0.015\text{ M NaCl}$ ,  $0.01\text{ M Tris-HCl}$ ,  $\text{pH } 7.4$ ) and centrifuged again for three successive washes. They were resuspended in RSB containing  $1\%$  Triton X-100 and gently homogenised by 10 strokes in a tight fitting Dounce homogeniser to prepare nuclei<sup>9</sup>. Nuclei were centrifuged for 1 min at  $1,800g$  and then resuspended in RSB and centrifuged three more times. The nuclear pellet was resuspended in RSB,  $\text{CaCl}_2$  added to a final concentration of  $10^{-3}\text{ M}$  and the suspension dispensed in  $0.4\text{ ml}$  quantities into tubes containing  $2\text{ }\mu\text{l}$  of micrococcal nuclease (Worthington, 40 units of enzyme to approximately  $10^4$  nuclei), and incubated at  $37^\circ\text{C}$ . Individual tubes were removed at various times, chilled on ice,  $100\text{ }\mu\text{g}$  carrier DNA added and the DNA precipitated with perchloric acid (PCA) at a final concentration of  $5\%$ . The supernatant was counted in  $7\text{ ml}$  water miscible liquid scintillation fluid (Aquasol). The precipitate was dissolved in  $5\%$  PCA at  $90^\circ\text{C}$  and counted in Aquasol. The fractions of  $^{14}\text{C}$  and  $^3\text{H}$  radioactivity rendered acid soluble by micrococcal nuclease was calculated from the radioactivity in supernatant and precipitate fractions from each tube.  $\square$ , Mean and standard error of  $^{14}\text{C}$ -Tdr uniformly-labelled cells.  $\circ$ , Labelled for 10 min with  $^3\text{H}$ -Tdr immediately after  $13\text{ J m}^{-2}$  ultraviolet light.  $\bullet$ , Labelled for 30 min immediately after  $13\text{ J m}^{-2}$  ultraviolet light.

**Table 1** Percentage of total radioactivity in the rapidly digested components of DNA in nuclei digested with micrococcal nuclease

Labelling and irradiation conditions	% Rapidly digested*		Repair replication†
	10	(10)	
Uniformly labelled $^{14}\text{C}$ -Tdr			—
Repaired, 10 min, immediately post UV	58	(2)	4
Repaired, 30 min, immediately post UV	33	(2)	14
Repaired, 30 min, immediately post UV‡	29	(1)	14
Repaired, 90 min, immediately post UV	19	(2)	53
Repaired, 4.5 h, immediately post UV	21	(2)	120
Repaired, 30 min, immediately post UV and grown for 5 h	35	(1)	—
Repaired, 10 min, immediately post UV and grown for 5 h	39	(1)	—

\*Values were calculated by extrapolation of the slow component of parallel curves similar to those shown in Fig. 2. Each value was obtained from the average of at least two separate determinations and is therefore not necessarily the same as the values that can be read off Fig. 2 since the latter illustrates single experimental determinations at each labelling time (the number in parentheses indicates number of separate degradation curves used to estimate this percentage).

†Amounts of repair replication expressed in arbitrary units calculated from experiments similar to those of Fig. 1, done for various labelling times.

‡Labelling done with  $^3\text{H}$ -Tdr but without hydroxyurea and FUdr.  
UV, ultraviolet irradiation.

in the precise labelling duration, because the nuclease digestion kinetics change rapidly during the shorter labelling periods. The distribution of repaired regions is therefore probably due to a faster rate and earlier completion of repair in inter-nucleosome DNA than in nucleosomal DNA.

In a previous study of the repair of alkylation damage in mouse cells Bodell<sup>12</sup> also showed that repair was concentrated on inter-nucleosomal DNA. In that study, however, it could be argued that there was either a non-uniform distribution of damage or a non-uniform distribution of repair, or both, because alkylating agents do not react with all regions of DNA to equal extents<sup>13</sup>. In the present study on the repair of ultra-violet damage it is most likely that the non-uniformity I have observed is due to the mechanism of repair, because pyrimidine dimers are caused by direct absorption of quanta of ultra-violet light in pyrimidine rings and the yield of photoproducts is insensitive to DNA conformation<sup>14</sup>. Some small effect of DNA structure on dimer formation which would result in a non-random distribution of dimers within or between nucleosomes cannot be completely excluded, however, but is unlikely.

These results (Fig. 2) can be interpreted to indicate that damaged DNA between nucleosomes is more rapidly repaired than DNA on the nucleosomes, this would explain many features of DNA repair previously observed. The size of the patch that replaces excised pyrimidine dimers, for example, has been usually estimated after long labelling times<sup>15, 16</sup>, after which most of the repair would be in regions of DNA on nucleosomes. Patch sizes estimated by a variety of methods seem to be about half the single-strand length of DNA associated with one nucleosome<sup>9, 10</sup>. This is what would be predicted if a randomly located dimer in a nucleosome is the starting point for an excision repair patch and the next nucleosome is the termination point. This model also predicts that the first excision repair patches made between nucleosomes after ultra-violet irradiation should have a much smaller patch size than those made later.

Several previous observations are consistent with a model in which excision repair is controlled by the structure of chromatin. Paterson *et al.*<sup>17</sup> found that excision of dimers occurred at two rates, an initial fast rate and a later slow one, and many studies on repair replication showed similar rate changes<sup>18-20</sup>. The possibility that dimers are not all equally accessible to repair enzymes was suggested by Wilkins and Hart<sup>7</sup> who showed that those dimers that were more rapidly excised from DNA were also more accessible to an exogenously supplied *Micrococcus luteus* 'ultraviolet specific' endonuclease. Mortelmans *et al.*<sup>8</sup> also showed that several complementation groups of the human DNA repair deficient disease xeroderma pigmentosum lack cofactors that control the repair of DNA in chromatin, rather than lack repair enzymes themselves as originally thought<sup>15, 21</sup>.

I conclude from these results (Fig. 2, Table 1), that the structure of mammalian chromatin exerts restraints on the rate of excision repair of ultraviolet-induced damage. In constructing models for excision repair it should, therefore, be considered that perhaps the substrate itself is the more complex entity rather than the association of repair enzymes, which has been frequently suggested<sup>22-24</sup>. The need for controlled access to damage in DNA may be one reason for the greater complexity of repair mechanisms in eukaryotes than in prokaryotes, which is indicated by the multiple complementation groups which affect excision-repair in xeroderma pigmentosum<sup>25, 26</sup>.

I thank Drs A. Blumenthal and Z. Werb for encouragement, Dr W. J. Bodell for providing unpublished manuscript on repair of alkylation damage, and Mr G. H. Thomas and W. Charles for technical assistance. This work was supported by the US ERDA.

## Anisotropy of the Young's modulus of bone

THE anisotropy in elastic deformation exhibited by compact bone sections is well known<sup>1</sup>, but has been demonstrated mainly for orientations parallel to, (designated as longitudinal) or, normal to, (designated as transverse or radial), the long axis of the bone. Various models based on the concept that bone is a hydroxyapatite-reinforced collagen composite have been proposed (for example ref. 2) to account for the elastic behaviour of compact bone, as defined by the Young's modulus ( $E$ ), but lack of data for a range of orientations has precluded one critical test of their validity. We report here preliminary measurements on the Young's modulus of mature bovine femur cortical bone for specimens orientated at various angles from 0° to 90° to the bone long axis. These results were obtained on a series of rectangular-shaped, machined, specimens (4 mm × 3 mm) with two different lengths (15 mm and 20 mm), by a novel differential ultrasonic technique, which is illustrated in Figs 1 and 2.

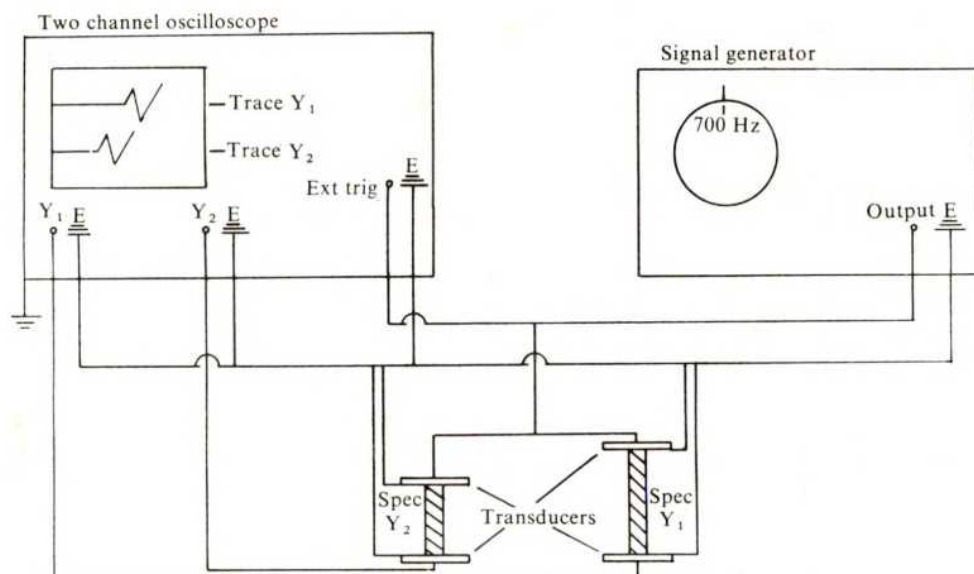

The time between the generation and receipt of a signal was measured (in  $\mu$ s) for specimens of 15 mm and 20 mm length, and as all other features of the circuit remained constant, the difference in time ( $dt$ ) for the two conditions was related to the difference in path length ( $dl$ ) provided by the bone specimens, and the velocity ( $v$ ) through the bone calculated. Assuming the path length in bone is isotropic, the Young's modulus ( $E$ ) is then derived from:—

$$\frac{dl}{dt} = v = \left( \frac{E}{\rho} \right)^{\frac{1}{2}} \quad (1)$$

where  $\rho$  is the specific gravity of bone<sup>1</sup>. This procedure was repeated for pairs of specimens orientated at various angles to the longitudinal axis (in a tangential rotation).

The absolute values of  $E$  calculated for the longitudinal (0°) orientation (17.3–19.7 GNm<sup>-2</sup>) are within the range of values (7–27 GNm<sup>-2</sup>) obtained by various workers<sup>1</sup> from the measurement of stress-strain curves, although smaller than a single value obtained on 'dry' bovine femur sections by an ultrasonic technique (26 GNm<sup>-2</sup>) (ref. 3). For the transverse orientation (90°), the calculated values of  $E$  (8.7–10.3 GNm<sup>-2</sup>) compare with values of 7.2 GNm<sup>-2</sup> (ref. 1) (stress-strain curve) and 13.2 GNm<sup>-2</sup> (ref. 4) (shock tube loading). The present results indicate that  $E_0/E_{90} = 2.3$  (dry) or 1.7 (wet), which agrees reasonably with previous findings<sup>1</sup> of a ratio of 1.9 (wet). These points of agreement suggest that the results obtained by the present technique are valid.

**Fig. 1** Circuit arrangement, with a signal through two specimens  $\gamma_1$  and  $\gamma_2$  producing traces  $\gamma_1$  and  $\gamma_2$ , respectively, on a two-channel oscilloscope.

No other results have been reported for the Young's modulus of bovine femur specimens orientated at angles of 5, 10, 20, 40, 50, 70, 80 and 85° to the long axis, which are shown in Fig. 3. The Young's modulus values at 0, 30, 60 and 90° compare with values of 23.1, 16.7, 12.8 and 10.4 GNm<sup>-2</sup>, respectively, measured by Reilly and Burstein<sup>5</sup>.

The significant finding of the present study is the experimentally-determined variation in Young's modulus with orientation, which exhibits a decrease in  $E$  from 0–20°, an approximate plateau from 20–70° (with a 'low' point at 50°) and another decrease from 70–90°. This result is in conflict with the predictions of a fibre-reinforced composite model, such as demon-

**Fig. 2** Details of the experimental arrangement of transducers and bone specimens, before and after mounting. (Specimens shown are not of the experimental dimensions.)

**Fig. 3** Variation in Young's modulus of bovine femur specimens ( $E$ ) with the orientation of specimen axis to the long axis of the bone, for wet (○) and dry (×) conditions compared with the theoretical curve (—) predicted from a fibre-reinforced composite model<sup>2</sup>.

strated by the theoretical curve<sup>2</sup> (derived for  $E_{0^\circ}/E_{90^\circ} = 10$ ) plotted for comparison in Fig. 3, which reveals a progressive reduction in the dependence of Young's modulus on orientation for values of  $E$  from  $\approx 10^\circ$  to  $90^\circ$ , with an almost constant value of  $E$  in the  $70^\circ$ – $90^\circ$  range.

We conclude, therefore that an alternative model is required to account for the dependence of Young's modulus on orientation. Further work is in progress to extend these results to a series of bones with different ultrastructures.

This research forms part of a project on the deformation and fracture of bone supported by the SRC.

## Nuclear phenomena and development

A. T. Sumner

*Nuclear Cytology in Relation to Development.* By F. d'Amato. Pp. viii+283. (Cambridge University: New York, London and Cambridge, 1977.) £15.

THE illustration on the jacket of this book of Balbiani rings on a polytene chromosome seems particularly appropriate for the subject of *Nuclear Cytology in Relation to Development*. In fact, Professor d'Amato takes his subject matter from a much wider field than this illustration might suggest. "Nuclear cytology" is regarded as ranging from molecular biology to cytogenetics; what one might regard as nuclear cytology in the strict sense—the detailed study of nuclear structure—does not occupy an important place in this book. Similarly, the subject of "development" is broadly interpreted. Evidently, although this is not stated in the preface, Professor d'Amato's aim has been to describe those nuclear phenomena which are associated with the many aspects of development. A refreshing and often illuminating aspect of his treatment of the subject is the balance of examples from both the plant and animal kingdoms.

The first chapter deals with life-cycles, especially the alternation of diploid and haploid phases, and certain aspects of fertilisation. Chapter 2, on the cell cycle, opens with a brief excursion into molecular biology, discussing DNA sequence complexity, as well as the different classes of RNA. It is disappointing to find that a book published in 1977 should regard histones as "general repressors of gene activity", while making no mention of their important structural role in nucleosomes. This section seems rather oddly placed at the beginning of a chapter very much concerned with factors influencing the duration of different stages of the cell cycle, although also treating various aspects of chromosome replication. From the cell cycle, d'Amato turns to a well integrated account of meiosis, with special consideration of meiosis in relation to parthenogenesis.

It is not at all clear why chapter 4,

on "Mosaics and Chimaeras" was included. Although the subject is of great relevance to several problems of development, no special nuclear phenomena are described here, apart from a short mention of chromatin elimination in cases of gonadosomic mosaicism. This chapter highlights a problem which recurs to a varying extent throughout the book. There are many excellent and well described examples in every chapter, but insufficient attempt has been made to explain their relevance to the chapter in which they occur, or to the book as a whole. Since, as already noted, the author does not clearly state his aim in writing the book, it is particularly important that a common theme should be evident throughout the book. Such a theme eventually appears as one reads the book, but there are places where it seems that the author's enthusiasm for certain topics has led to considerable digressions.

The remaining half of this book sticks more closely to what seems to be its main theme: nuclear phenomena correlated with development. Two chapters deal with changes in nuclear DNA content during development: one with increases of the whole chromosome complement (essentially polyploidy and polyteny), and the other with differential DNA replication. There is much of interest in both these chapters, and the author's practice of taking examples from a wide variety of organisms is of particular advantage here. Evidently, DNA amplification, either selective or total, may be more important in differentiation than I. for one, had supposed.

Next come two chapters which cover what one might regard as the essence of a study of the nucleus in relation to development: gene expression and its regulation. It is axiomatic, as d'Amato clearly states, that differentiation must be viewed in terms of gene expression. Although none of the nuclear changes described earlier in this book can be causally related to differentiation, it is clear that single somatic nuclei of plants and (as described in the final chapter) of animals

contain all the genetic information necessary for normal development. d'Amato's consideration of gene expression concentrates on the localisation by *in situ* hybridisation of repeated genes, and on transcription in lampbrush and polytene chromosomes. These latter aspects could perhaps have been treated more extensively with advantage, for here are two types of chromosomes which afford unrivalled material for the study of nuclear cytology in relation to development. It is, moreover, a section which calls for half-tone illustrations, of which there are none in the book. If these were rejected on grounds of expense, it seems a false economy. (The book is nevertheless well illustrated by line drawings.) In the following chapters, the roles of heterochromatin, histones, and non-histone chromosomal proteins in gene regulation are considered, with the growing evidence for the importance of the latter being clearly brought out. The final chapter, "Regeneration and Totipotency," brings together information interesting in its own right, including the exciting experiments on nuclear transplantation in amphibia. This work, showing that nuclei of differentiated somatic cells still contain all the information necessary to produce a complete adult organism, is now such a cornerstone of developmental biology that it deserves an earlier and more prominent place in this book.

In conclusion, Professor d'Amato has brought together a wealth of information on the changes which occur in cell nuclei in different developmental situations. This is reflected in a bibliography of (the publisher tells us) over 1100 references, occupying nearly 50 pages. One wishes that the author had taken more space for general comment to integrate his material. Nevertheless, this is a book in which the specialist may well see new light shining on old problems, and the non-specialist read profitably for general information. • □

## Electron spectroscopy

*Electron Spectroscopy: Theory, Techniques and Applications*. Vol. 1. Edited by C. R. Brundle and A. D. Baker. Pp. xv+459. (Academic: New York and London, 1977.) £24; \$46.90.

A MAJOR EFFORT to survey the present situation in electron spectroscopy has been undertaken by some of its more prominent explorers under the editorship of Drs C. R. Brundle and A. D. Baker. The material is distributed in three volumes, the first of which is now ready. To get a balanced impression of the total work one would have to await the other two volumes, since much basic and important material is still left to be treated in these forthcoming volumes. Already, after going through the first volume, one is, however, in a good position to see that this work will become an indispensable source of knowledge for all investigators in the field.

After an introduction to electron spectroscopy by the two editors, the present many-electron theory of photoelectron emission is reviewed by R. L. Martin and D. A. Shirley. The authors have themselves contributed a good deal to some of the conceptual parts of the theory for electron emission processes. After reading this and the next chapter by W. L. Jolly—treating his equivalent cores approximation—the reader should have obtained a good understanding of some of the main topics, which underlay most applications. W. C. Price, well known as an authority in 'classical' ultraviolet photon spectroscopy for molecules before photoelectron spectroscopy had appeared and also as one who has given distinct impetus to present-day photoelectron spectroscopy, treats the latter as applied to small molecules. Particularly interesting is his discussion as to why previous emission and absorption photon spectroscopy failed to reproduce the molecular electron level systems. He concludes his chapter thus: "In the brief period in which it has been developed, photoelectron spectroscopy has had phenomenal success in revealing the electronic structure of matter in a particularly direct way. Chemists can see the orbital structure of even fairly large molecules and no longer have to rely on the predictions of theoreticians. Future advances in the study of solids, adsorbed species, etc., can confidently be predicted to yield information on the nature and functions of the electrons involved. It is also clear that the subject will provide a happy hunting ground

for the physicist as well as the chemist for many years to come."

It is gratifying to see that indeed many chemists are already on the hunting ground and with most rewarding results. One of the great hunters is no doubt E. Heilbronner who, together with his colleague J. P. Maier in the next chapter, gives many illustrative examples from his rich scientific experience in the field of organic chemistry. A corresponding account from inorganic chemistry is amply given by R. L. DeKock, written, according to the editors' preface, during his stay in Beirut during "the troubled period of civil strife in Lebanon!"

High temperature studies of ultraviolet-excited electron spectra from

## World food supply problem

*World Food Resources: Actual and Potential*. By Michael Allaby. Pp.vii+418. (Applied Science: London, 1977.) £15.

THIS 'popular', readable, fact-packed book is presumably aimed at the 'informed layman'. But much of it should interest the scientist, agriculturalist or economist who wishes to see his speciality in better perspective. After an introductory chapter, comes a useful chapter (2) on population and on (economic as distinct from biological) food demand, followed by two chapters on regional nutritional status, the cost of 'modernising' farming, the 'green revolution', soils, water and fertilisers (3 and 4). Two historical chapters (5 and 6) are too UK-based to be useful. There then follow helpful chapters (7-9) about 'advanced' farming and its dependence on non-solar energy inputs, on its genetic vulnerability, on its ecological side-effects, and about alternative farm technologies.

An interesting chapter (10) on fish is followed by one (11) on land reform, rural employment, farm credit, and so on, and the *possible* (reviewer's italics) means of raising incomes and food production. Nevertheless, "we cannot be certain that those most in need of food will receive it" (p357). The final chapters (12 and 13) are politico-economic and examine the likelihood that effective international trade, aid and monetary devices would help to secure food for the under-fed, for example, by making phosphatic fertiliser available to poor countries.

Allaby, if not pessimistic, is doubtful about the likelihood of positive international action (chapter 13). But such doubts, one feels, are challenges to

halides is treated by one of the pioneers in this advanced form of the spectroscopy, J. Berkowitz, and the volume ends with a chapter on two-parameter coincidence experiments by M. E. Gellender and A. D. Baker. This technique, as pointed out by the authors, is more tedious than the usual electron spectroscopy but is instead applicable to, for example, ions of chosen excitation energies.

The applications of electron spectroscopy are expanding rapidly and already there is a problem to keep abreast with achievements in various fields. The present high quality volume is most helpful in this respect.

Kai Siegbahn

Kai Siegbahn is Professor in the Fysiska Institutionen, Uppsala, Sweden.

those scientists and agriculturalists who are, for instance, seeking techniques to make available to crop plants the phosphate that is now immobilised in the soil, or to raise the lysine content of maize or sorghum, or to devise more productive farming systems (for example, the work at the International Institute of Tropical Agriculture, Ibadan, Nigeria). Allaby fails, it seems, to appreciate the scope for increasing, by relatively inexpensive means, the efficiency of human food chains. A major function of those trying to raise such efficiency should be, one feels, to make food production and consumption in poor countries as biologically independent as possible both of income gradients and of international squabbles, ideological differences, economic collapses and weather disasters.

The book as a whole lacks editorial discipline: chapter titles could be less 'slick' and more descriptive; more subtitles in the text would help the reader; not all the many tables are necessary although some of them, it must be said, are not available elsewhere in printed form. The references are inconsistently presented (some on tables, some at chapter ends, some in the Bibliography) and at least one is missing. Finally, many of the frequent acronyms are not defined or are enigmatic except to those who just happen to know, for example, that FAO/IWP means the Indicative World Food Plan (IWP) issued by the United Nations Food and Agricultural Organisation (FAO) in 1970.

This is a readable and useful, but sometimes diffuse, confusing and perhaps unduly pessimistic contribution on the world food supply problem. A much shorter, more disciplined version would be of greater use to the scientific community. A. N. Duckham

A. N. Duckham is Emeritus Professor of Agriculture at the University of Reading, UK.

## Evolution updated

*Evolution.* By T. Dobzhansky, F. J. Ayala, G. L. Stebbins and J. W. Valentine. Pp. 572 (Freeman: San Francisco and Reading, 1977.) £11.60.

EACH co-author has written four chapters in this book, setting forth his own ideas, and reflecting his own involvement with biology and genetics. I have a feeling that this has inevitably, although inadvertently, resulted in some overlap, not necessarily of illustrative material, but in the broad outlines of the ground covered. As might be expected, the most lucid passages are by Dobzhansky, to whose memory the book is dedicated. A notable 'one-liner' by him, "Nothing in biology makes sense except in the light of evolution", is on a flyleaf following the title page.

The chapter titles are as follows: "The Nature of Evolution", "Patterns of Speciation", "Evolution of Prokaryotes and Unicellular Eukaryotes", and "The Future of Evolution" by Stebbins; "The Genetic Structure of Populations", "The Origin of Hereditary Variation", "Phylogenies and Macromolecules", and "Philosophical Issues" by Ayala; "Natural Selection", "Populations, Races, Sub-species", "Species and Their Origins", and "Evolution of Mankind" by Dobzhansky; "Transspecific Evolution", "The Geological Record", "Cosmic Evolution and the Origin of Life", and "The Evolutionary History of Metazoa" by Valentine. These widely ranging topics certainly provide ample basis for a sweeping treatment of evolution.

Molecular matters have apparently been assigned to Ayala, who is a population geneticist. He also describes his studies of polymorphism in *Drosophila* populations of various localities. Valentine is a geologist and palaeobiologist, and he has provided an excellent discussion of the fossil record of evolutionary rates, and the record of ancient life and environment, including a welcome section on plate tectonics. Stebbins and Dobzhansky are both well known as authors of books and treatises on evolution.

In commenting on the 'evolutionary clock', Ayala discusses (p309) the comparison of amino acid differences between  $\alpha$ -haemoglobins of mammals and carp. He says that "the most recent ancestor to the four-legged mammals lived some 70 million years ago", and therefore he concludes that the comparison is useful for only 10% of the 700 million years of evolution of the  $\alpha$  chain. But this contention overlooks the fact that  $\alpha$ -haemoglobin sequences are also available for kangaroo, echidna, chicken,

viper and newt, and these fall in the intervening years. Ayala (p309) notes that differences between  $\alpha$ -haemoglobins of man and mice (17) are less than between rabbits and mice (28). (These differences are actually 16 and 27.) From this, he speculates that the rates of amino acid replacement may be increased by shorter generation time. The data he cites, however, are too scanty. If the  $\beta$  chains are compared, the man-mouse difference is 28 and the rabbit-mouse difference is 29.

The subject of evolution embraces both the past and future of human beings. It therefore presents an irresistible temptation to indulge in philosophical discourse. Three of the authors have availed themselves of this opportunity, and Ayala holds forth on "Philosophical Issues" for the final 42 pages, in which he provides us with such insights as "Common sense tells one that children resemble their parents and that good seeds produce good crops", and "No organism can be truly independent of the environment". I felt that Stebbins, and, more especially, Dobzhansky, had provided sufficient (and excellent) treatment of dissertational matters in chapters 14 and 15, so that the last chapter was not needed.

In a comparison of cytochrome sequences, the table on pages 296 and 297 shows only 20 identical positions shaded in grey, but 36 positions should have been so indicated. In addition, the

sequence of residues 27-34 in *Neurospora* cytochrome is erroneous.

Figure 2-3, page 26, depicts the anticodors for UUU and GGU as AAA and ACC. These should be GAA and GCC. Figure 3-1 shows an erroneous codon for methionine, and represents purines by "Y", which is the symbol for pyrimidines.

All in all, the book is an excellent and up-to-date treatment of evolution, the subject that has spread like a network to encompass all the biological sciences. I could not help contrasting the wealth of material in this book with the fact that creationists are still largely successful in their efforts to minimise the teaching of evolution in schools in the USA. In June 1977, a member of the California State Board of Education was able to expunge or garble certain sentences descriptive of evolution in the forthcoming new edition of *Science Framework*, a booklet of guidelines for teaching science. For, as Dobzhansky says (p439): "The mutually sustaining effects of biologists, paleontologists and anthropologists have made the theory of the evolutionary descent (or rather, ascent) of man impregnable . . . And yet some antievolutionists persist. Some of them are simply ignorant of the evidence, while others have so prejudged the question that no evidence is meaningful to them".

Thomas H. Jukes

Thomas Jukes is Professor of Medical Physics at the University of California at Berkeley.

## Botanical heritage

*Dictionary of British and Irish Botanists and Horticulturists: Including Plant Collectors and Botanical Artists.* By Ray Desmond. Pp. xxvi+747. (Taylor and Francis: London, 1977.) £40.

If there is one area in which the British Isles has been highly productive, it is in the generation of botanists, yet few of their names have survived except possibly in the specific names of certain obscure plants. Names like Ray, Gerard, Turner and Culpeper may still be familiar to many, especially those caught up in the recent general enthusiasm for health foods, herbs, and so on. But many more names have now passed into oblivion as botanical exploration and taxonomy have progressed. This *Dictionary* has grown out of a desire to catalogue our British and Irish botanical heritage and to collate what information can be recovered concerning the achievements of our deceased, plant-hunting forefathers.

Each entry is set out in the form of details of date and place of birth and death, education, qualification and

selected publications. Information concerning biographies, obituaries, herbaria and species graced with the botanist's name are also given in abbreviated form. Only dead botanists are included, but all spheres of the subject are covered, from nurserymen to palaeobotanists and physiologists.

The obvious question one must ask when faced with this hefty and expensive tome, concerns the use to which the book may be put. It is not a collection of historical anecdotes, and will not, therefore, serve as a book into which one may dip for entertainment. Its value is likely to be appreciated only by those undertaking serious historical studies into the development of botany in Britain. It is a book which will thus find its way into specialist libraries, but at this price it is hardly likely to attract the attention of individual botanists. It is essentially a work of reference which will lead the historically minded to obscure sources which would not otherwise be easily traced.

Peter D. Moore

Peter Moore is Senior Lecturer in Plant Sciences at King's College, University of London, UK.

## Neutron scattering

*Neutron Scattering in Chemistry.* By G. E. Bacon. Pp. 186. (Butterworth: London and Boston, Massachusetts, 1977.) £12.50.

IN writing this book, Professor Bacon has attempted a very difficult task. It is difficult firstly because any technique is likely to be able to contribute to many different branches of chemistry and secondly because neutron scattering is several techniques rolled into one. On the one hand, it is a structural tool and so immediately embraces the whole range of structural work on condensed matter including crystallography. In addition, however, the magnetic dipole moment of the neutron makes possible the study of magnetic structures and hence the determination of unpaired spin densities. On the other hand, it is also a spectroscopic technique because the low energy of neutrons of wavelength comparable with molecular dimensions makes possible an energy analysis of scattered neutrons so as to reveal details of atomic and molecular translational, rotational and vibrational motions. It is this unique ability to probe explicitly the time-dependent structure that makes neutron scattering so powerful. The range of problems which can usefully be studied, however, is always limited by the available neutron fluxes.

For many years, it has been possible to study relatively complex structures but when the fourth dimension of energy analysis is added the flux determines the practicable energy resolution and therefore the complexity of the problem which is amenable to study. A major advance in this respect was provided by the advent of the latest generation of high flux reactors within the past few years, and in particular the unique instruments at the Institut Laue Langevin, Grenoble. It is unfortunate that the timing of this book is such that only a very little of this exciting new work could be included.

Professor Bacon (a Professor of Physics) has attempted to give a brief (~ 180 pages) and essentially qualitative description of some of the results of applying neutron scattering techniques to various areas of chemical interest. It is a book in which to find a summary of some of the things which have been or can be done using neutrons, rather than a detailed description of the underlying theory or of the chemistry. For the reader who wishes to pursue a topic to a greater depth, there is a general bibliography of neutron scattering texts and conference proceedings and a list of references with each chapter.

The first two chapters contain good, succinct descriptions, respectively, of the

Principles of Neutron Scattering and Experimental Methods. Three chapters follow on crystallographic studies (Structural Studies, Direct Methods, and Correlation of X-Ray and Neutron Data: X-N Syntheses) which contain some well-chosen examples of recent work. A brief chapter on Studies of Biological Materials contains a timely discussion of small angle scattering methods, but it is surprising to find no mention of specifically chemical applications of these techniques, such as the important studies of polymeric materials. Two further chapters complete the discussion of crystal structure investigations; the first (Measurements of Covalency) is concerned with magnetic scattering and the second with both Bragg reflection and diffuse scattering studies of Defects and Non-Stoichiometry in a variety of crystalline phases.

In all of the above, as well as in the structural aspects considered in the last chapter on Liquids, Glasses and Gases the treatment is clear and authoritative. The two chapters not so far mentioned are entitled Molecular Spectroscopy and

Polymers. Here, the treatment is less satisfactory partly because, as mentioned earlier, it is in these areas where marked advances have very recently been made, since the availability of high resolution spectrometers. Nevertheless, this does not account for all the omissions: for example, there is no discussion of quasielastic scattering from molecular rotations, nor of solid-state diffusion; indeed, the treatment of quasielastic scattering does not begin to reflect the importance of this area of work (the omission of any reference to Springer's elegant 1972 monograph on the subject demonstrates the point). There should have been some mention of phase transitions and a more extensive discussion of phonon dispersion in molecular crystals. In spite of the omissions, however, this is a timely and welcome book which goes some way towards filling a serious need

A. J. Leadbetter

*A. J. Leadbetter is Professor of Physical Chemistry at the University of Exeter, UK.*

## Raman spectroscopy

*Raman Spectroscopy.* By D. A. Long. Pp. xiii+276. (McGraw-Hill: New York and London, 1977.) £14.40.

FOLLOWING the development of the laser in the early 1960s, there has been a boom in Raman spectroscopy. It is now a routine laboratory technique. This rapid progress has led to the publication of several multi-author volumes and to the *Journal of Raman Spectroscopy*. This book, however, is the first by a single author that aims to provide an "up-to-date survey of the whole subject, setting Raman spectroscopy in perspective, unifying the basic theory, illustrating the applications and potential of the technique, and guiding the reader towards the specialist literature".

There are eight chapters and three appendices. Also, there is a central reference section of sixteen blue pages containing thirteen tables of formulae for intensities and polarisation properties of Raman scattering by gases. Chapter 1 is a general introduction, a nice feature being the reproduction of the original 1928 papers by C. V. Raman and K. S. Krishnan and by G. Landsberg and L. Mandelstam in *Nature* and *Naturwissenschaften*, respectively. Chapter 2 describes the properties of electromagnetic radiation and defines the four Stokes parameters. Chapters 3 and 4 present classical and partial quantum-mechanical treatments of Rayleigh and Raman scattering. They proceed at an easy pace and include a very detailed account of the

polarisability tensor. Chapter 5 is on time-dependent perturbation theory, the Placzek polarisability theory, resonance Raman scattering, and Raman optical activity. Experimental procedures are described in chapter 6 and numerous examples are discussed in chapter 7. The final chapter is devoted to non-linear Raman effects. Appendix I is a guide to the literature; II lists for the common point groups the symmetry classes of translations, rotations, polarisabilities and first hyperpolarisabilities; and III describes a Raman study of a crystal.

The style is lucid and the illustrations excellent (although the notation is not always attractive), so the book will be helpful to many students. It expounds at length some of the properties of cartesian tensors, and includes some very interesting and recent applications of Raman spectroscopy to problems in organic and inorganic chemistry. Some of the more physical topics, such as line shapes and Brillouin scattering from liquids, are not considered. In a few places, as in the description of magnetic and electric Raman optical activity on p131, there are errors; and the references are not always adequate (for example, the four references at the end of chapter 3 and those in Appendix I give no help to someone trying to understand non-linear polarisation, introduced on p41).

The book has been well produced and is good value.

A. D. Buckingham

*A. D. Buckingham is Professor of Chemistry at the University of Cambridge, UK.*

# obituary

## Gersh Budker

PROFESSOR Gersh Itskovich Budker, Director of the Institute of Nuclear Physics of the Siberian Branch of the Soviet Academy of Sciences, died on 5 July 1977. With his death we have lost one of the most imaginative and colourful accelerator scientists.

Professor Budker was born on 1 May 1918 in the Ukraine. He graduated from Moscow University in 1941 and, after having served in the Soviet Army until 1945, began work at the Institute of Atomic Energy of the USSR Academy of Sciences. He was initially involved in nuclear reactor development but his interests gradually moved to accelerators for elementary particle research. In 1956 he also became professor at the Moscow Engineering Physics Institute.

In the same year the Scientific Research and Educational Centre, Akademgorodok, was created just outside Novosibirsk. This was a great challenge to creative young scientists, and it was natural that Budker, in 1957, was appointed director of its Institute of Nuclear Physics. This Institute has been the source of an almost continuous stream of ideas and novel accelerator systems and very soon became known throughout the world.

In his new position Budker was able to realise some of the plans he had already developed while at the Kurchatov Institute in Moscow. His main theme was to provide colliding-beam facilities so as to bring his institute to the forefront of elementary particle physics without the heavy expenses required for more conventional accelerators. He was not only afraid of great expense (he even sold accelerators in the 'open' market to boost his budgets), but also afraid of the inflexibility inherent in very large installations. The programme he established was ambitious and daring and made heavy demands on ingenuity and drive.

He had his first storage ring, VEP-1, working in 1963. An electron-positron device, VEPP-2 of  $2 \times 700$  MeV, was in operation from 1967, another one, VEPP-3 of  $2 \times 2.2$  GeV, in 1972, and a fourth one, VEPP-4 of  $2 \times 7$  GeV, is at present under construction. They have made it possible for his institute to

Camera Press

perform front-line experiments on meson resonances. Some of the rings have also been used as a source of synchrotron radiation for research in solid state physics, etc.

Budker had incorporated a two-way proton colliding beam device in the original plans for his Institute. He modified this in 1966 when he invented the so-called electron cooling of proton or antiproton beams, which made it feasible to propose instead a colliding beam project with antiprotons against protons. The electron cooling technique was essential for the accumulation of sufficiently intense beams of antiprotons.

But first the cooling principle had to be verified experimentally. With the limited means available at the institute this took longer than Budker had hoped and delayed the proton-antiproton plans. However, in 1974 his institute could report most beautiful experimental evidence for electron cooling of a proton beam. This invention and its experimental verification must be considered the peak of Budker's career. The technique and its possible uses are being discussed in accelerator laboratories all over the world, and it is being considered in important plans both at the European Organisation for Nuclear Research, CERN, and at the Fermi National Accelerator Laboratory in the United States.

Although Budker and his institute became best known because of the work on accelerator devices, the institute also has a branch that carries out research in plasma physics, which gives a very fruitful cross-fertilization between plasma physics and accelerator physics.

Professor Budker distinguished himself not only as a scientist, but also through his exceptional ability to stimulate and inspire his collaborators. His Institute is now 20 years old and has many remarkable achievements behind it. Nevertheless, it still retains an unusual pioneering spirit. Budker also felt very deeply about the whole philosophy that lay behind Akademgorodok and was a driving force in ensuring that this unique place became a centre of scientific achievements with a world-wide reputation.

Budker was a member of the USSR Academy of Sciences. In 1967 he received the Lenin Prize for his contributions to the development of colliding beam devices.

## Milton N. Bramlette

MILTON NUNN BRAMLETTE, the distinguished American geologist, died on 31 March, 1977. He was born in Bonham, Texas, on 8 February, 1896, attended preparatory school in St. Louis, and entered the University of Wisconsin, Madison, in 1914.

His university studies were interrupted by World War 1. He enlisted in the aviation service, and qualified as a pilot, but too late in the war for combat service. He was discharged early in 1919 as a 2nd Lieutenant, and returned to Madison, where he graduated A.B. in 1921. During two summers he had served as assistant on the Wisconsin Geological Survey, running magnetic traverses across the iron ranges of northern Wisconsin.

With this field experience and high academic record, he was appointed Assistant Geologist in the U.S. Geological Survey in 1921. While headquartered in Washington he commuted to Johns Hopkins for advanced work in stratigraphy. After field mapping in Montana, Kansas and South Dakota, he took leave of the Survey

for graduate work at Yale. This was interrupted by field work in Mexico and Venezuela for the Gulf Oil Company. He returned to Yale for further graduate studies in 1928–1930, when he resumed his appointment with the Geological Survey. His doctorate was received *in absentia* in 1936.

Bramlette soon entered into a close and remarkably fruitful association with that outstanding specialist in Mollusca, Wendell P. Woodring, for a series of brilliant stratigraphic studies in California: the Palos Verdes Hills, Kettleman Hills and Santa Maria Valley. It was then that Bramlette began his petrological studies of the sedimentary rocks, dealing especially with intrastratal alterations, phosphates, zeolites and siliceous cements, culminating in his classic paper on the cherts of the Monterey Formation. He also began his studies of Cenozoic micropalaeontology and with his keen discernment was soon able to identify many of the diagnostic foraminifera in the field with a hand lens.

Bramlette was a principal investigator, along with W. H. Bradley and K. E. Lohman, of the transatlantic series of Piggott cores during the 1930's. With our current plethora of much longer deep sea cores, this work has been nearly forgotten; nevertheless it was the first study of deep-sea stratigraphy and was highly significant in permitting the first correlation of European and American glaciations. At this time he laid the groundwork, through his studies of the Arkansas bauxite deposits, for the great increase in productivity of these mines during the submarine-induced crisis of the second world war.

In 1940 Bramlette joined the faculty of the University of California at Los Angeles, where he remained until his transfer to the Scripps Institution of Oceanography in 1951, except for two years during World War II, when he worked on the bauxite deposits of Arkansas and Jamaica.

At the Scripps Institution Bramlette began his highly rewarding studies of the fossil coccoliths. Because of their minute size and irregular forms, these organisms sink very slowly in the sea so that currents distribute them almost world-wide. Accordingly they constitute unusually valuable time markers for the widespread correlations of marine sediments. Bramlette's contribution to the development of such correlations was pre-eminent, and he continued as a world leader long after his formal retirement in 1964.

Bramlette's versatility and profound scholarship were outstanding. He was elected to the National Academy of Sciences in 1954, was awarded its Thompson Medal in 1964, the Distinguished Service Medal of the Depart-

ment of the Interior in 1963, and the Doctor of Laws degree from the University of California in 1965.

He died of emphysema on March 31, 1977. He was a modest gentleman.

James Gilluly

## A. L. Walpole

DR ARTHUR WALPOLE died at Wilmslow, Cheshire on 2 July 1977, aged 64. Trained initially as a chemist (Imperial College London, B.Sc., Ph.D.), he spent a short period in the Department of Pharmacology, Edinburgh, and then joined the biological section of the new pioneer group in the Dyestuffs Division of ICI Ltd, in Manchester, which ultimately became the Pharmaceuticals Division.

His early interest, on the implication of novel synthetic oestrogens in the treatment of tumours, coupled with the appointment of Professor (later Sir) Alexander Haddow as a consultant, began Walpole's concern with cancer research, for which he is best known. His work fell under two headings. First came his collaboration with Michael Williams, who as Medical Officer for the Dyestuffs Division was deeply involved in its associated industrial hazards. Together over the years, with *ad hoc* synthesis where needed, they worked out structure/carcinogenic relationships, particularly amongst the arylamines, which still remain of world-wide significance.

Alongside this, and arising in part from the textile interests of the Division, Walpole was amongst the earliest (1947 onwards) to study the effect of introducing alkylating groups such as methylolamido, epoxide and aziridyl into potential tumour-inhibitory structures. His recognition of the peculiar cytotoxic properties induced by these moieties again had implications for industrial safety.

Walpole's other over-riding interest was in the hormonal control of reproduction and related phenomena. Thus researches around basic derivatives of the oestrogenic triphenylethylenes have recently led to a compound especially useful in the treatment of certain forms of mammary carcinoma. Likewise, he pioneered parallel studies in animal husbandry, first using certain disthioureas, and later the new synthetic prostaglandins. He was engaged on this latter work at the time of his death, two years after formal retirement.

As a person, he naturally attracted a wide circle of friends and collaborators, and his other qualities extended deeply

into the arts. Above all, he was much concerned for humanity, whether in the mass or the individual. He leaves a widow, Dora.

F. L. Rose

## G. G. Villela

PROFESSOR Gilberto G. Villela, the founder of modern biochemistry in Brazil, died on 17 July 1977, aged 73.

Dr Villela was born in Minas Gerais, Brazil, on 12 July 1904. After graduating in medicine in 1926 he entered the Oswaldo Cruz Institute with which he was associated, first as a student and then as a member of the staff, until the time of his death.

Dr Villela was an authority in the field of biochemistry and he made many significant contributions specially in vitaminology and enzymology. Another field of active interest was the biochromes, where he made many contributions to the study of animal pigments. His publications, more than 300 papers, appeared in medical and biochemical journals in Brazil, Britain, the United States and elsewhere. He was also the author of several scientific books.

Dr Villela visited, lectured and carried out scientific work at many important research centres all over the world, including the University of California Medical School (1945), University College London (1949), the Pasteur Institute (1950), and New York University (1961), where he was a Visiting Professor. As a UNESCO representative he set up a new centre of biological research at the University of Rangoon, Burma (1967). More recently he went to Japan as a lecturer, at the University of Nagoya (1973) and as Chairman of the Xth International Congress of Nutrition in Kyoto (1975).

Dr Villela was elected to several international scientific societies and received several medals and prizes. He was the founder and first President of the Brazilian Society of Biochemistry, and attended most of the Society's meetings.

Dr Villela's life was fully devoted to his scientific interests which he pursued with enthusiasm and vigour. To his co-workers and students he was an inspiring and ever-helpful teacher. He enjoyed discussions; his mind was very critical but combined with a good sense of humour. He was a man of high moral standing and humanistic education. He will always be warmly remembered by all who knew him.

He is survived by his widow Regina, one son, Gilberto, one married daughter, Sonia and a grandson, Pedro.

Emilio Mitidieri

8 December 1977

## Don't squander precious time on genes

THE House of Commons Select Committee on Science and Technology is one of Britain's more valuable Parliamentary institutions. In the past it has held a number of important and useful inquiries—into Lord Rothschild's proposals for reorganising research council funding, for example, and Britain's choice of nuclear reactors. Even if the conclusions of such inquiries have been open to criticism, they have often thrown much-needed light on some of the murkier corners of government decision-making.

It is, however, difficult to be entirely enthusiastic about the select committee's decision last week to establish a sub-committee on genetic engineering—which presumably means the implications of current research using recombinant DNA techniques. Not that the subject lacks widespread public concern (perhaps more so in the United States than in Britain), nor that it is one on which politicians, in whose lap some of the important decisions may ultimately fall, are well informed. But the timing is wrong.

It is now over three years since the moratorium on recombinant DNA was announced by a group of scientists in the US, and in that time much has happened. Every country which carries out such experiments has now developed some form of control mechanism (some, admittedly, more effective than others). And in the process, the issues

raised by the experiments have been subject to exhaustive scrutiny and debate. As a result, there now seems to be a general feeling that initial reactions may have been too strong. This cooling-off has undoubtedly been partly due to the successful lobbying of those with scientific and other interests in the continuation of such experiments. But there is also a general feeling among many scientists that the dangers, although real and potentially extremely hazardous, have been overplayed.

In these circumstances, it is difficult to see what the select committee will be able to achieve. The area is not one which, like some previous issues, can claim to have suffered from lack of public debate. This is not to claim any particular immunity for decision-making processes within the scientific community. But although such an inquiry would have been useful two years ago, there seem to be more pressing and potentially significant issues at the present time. Examples might be the future needs for scientific manpower, or the definition and management of technological risk in general (which might, indeed, still be embraced by expanding the terms of reference of the new subcommittee). The select committee's time is a precious commodity; it would be a pity if it was squandered on re-opening the scars of previous battles. □

## China's path ahead

WE bring together in this issue of *Nature* a number of reports on recent developments in science within the People's Republic of China, together with a note on the Peking/Taipei conflict, which is at present reverberating within the international unions. Some of the barriers between the People's Republic and the rest of the world were lifted five years ago. Yet it is still possible for the Chinese to spring surprises on us—with their great wealth of data, their respect for the role of the amateur in some scientific fields, and most recently with the obvious signs of a profound interest in re-establishing science and technology as a thoroughly professional pursuit. This latter trend can be seen not only in the way that university and institutional research is being revived for the purpose of obtaining economic benefits for the nation, but also in the way that certain selected branches of science with less obvious practical benefits are to be stimulated. The all-China meeting in the Spring to discuss national policies on science and technology is bound to be a fascinating occasion.

The path ahead for China is by no means simple, however. Renewing a respect for pure research, for theoretical

understanding as well as practical achievement, even for an elitist rather than populist approach, will not be easy after half a generation in which many of the invisible threads of tradition in the scientific method may have been damaged. But perhaps an even more difficult task will be for the Chinese to hold fast to those elements of people's science which have proved so successful in recent years, most notably the accurate reporting of natural phenomena whether they be connected with health, agriculture or stirrings within the earth. For in some instances this mobilisation of the masses has had major successes—the use of amateur scientists in earthquake prediction, for instance, with many quakes now successfully predicted, puts the Chinese well ahead of the rest of the world.

How maintain a broad public involvement in science and technology while giving the experts their head? And how cope with an almost inevitable demand from a newly-arisen intelligentsia for a greater extension of human rights and liberties? These are among the questions that China must confront in the next decade with its new mood of enthusiasm for science. □

# Science in Hua's China

## The key to modernisation

Science is undergoing a renaissance in post-Mao China. The United States National Academy of Sciences has been keeping track of the changes, as **Mary Brown Bullock** reports

IN recent months many visitors to China, and the Chinese press, have been recording a dramatic change in China's science and technology policy. Since the "smashing of the gang of four", China has embarked on a pragmatic drive to achieve the "four modernisations"—industry, agriculture, national defence, and science and technology—by the year 2000. The significant aspect of the current use of this slogan is the new emphasis being placed on science and technology as, in Chinese parlance, the "key link" in supporting the other three sectors.

The scientific renewal has been explicitly endorsed in speeches by Chairman Hua Kuo-feng and Vice-Premier Teng Hsiao-p'ing. It has also been evident in a spate of Chinese newspaper articles, scientific conferences and meetings, with the promise of more to come. As a result the broad outline of China's revitalised science policy have become evident.

The new focus includes basic re-

search, selective learning from foreign sources, specialised graduate training, and a new respect for professionalism. In the terms of China's 25-year-old science policy debate, the tension between "reds" and "experts" has eased. Both the masses and the professionals have contributions to make, but the cutting edge has returned to the experts.

Some of these trends were observed by a high-level delegation of American scientists led by Dr Philip Handler, President of the National Academy of Sciences, and sponsored by the Committee on Scholarly Communication with the People's Republic of China, which visited China in June. During visits to five universities and more than 25 research institutes in Peking, Tsingtao, Wuhan, Shanghai, and Nanking, delegation members observed new vitality in research institutes, planning for more specialised graduate education, and a greatly strengthened role for the Chinese Academy of Sciences.

These early impressionistic observations have been confirmed during the past four months by the political reinstatement of China's patron of science and technology, Teng Hsiao-p'ing, by official policies promulgated by the 11th Party Congress, and by numerous articles in the Chinese press. Furthermore, the selection as a member of the Politburo of Fang I, Vice-President of the Chinese Academy of Sciences, has continued to enhance the position of the Academy.

A ministry-ranked institution, the Academy is now being assigned a major role in providing the scientific and technical expertise necessary to modernise agriculture, industry, and national defence. The Academy's research institutes, of which there are over 60, and which were formerly under attack for their 'elitism', now receive encouragement and support from central and local authorities.

### New policies

Two articles by leading Chinese scientists published in the authoritative, and usually political, *Red Flag*, reflect a number of the new policies. The first, entitled 'Science and technology must catch up with and surpass advanced world levels before the end of the century', was written by Chien Hsueh-sen, a former aerodynamics and rocket expert at California Institute of Technology, who returned to China in 1955. Published in early July as one of the first detailed discussions of China's new science policy, the emergence of the western-trained Chien as official spokesman itself symbolised a major change.

In a rather candid portrayal, Chien acknowledged a disparity between the state of Chinese and world science. But he went on to affirm that China could catch up through selective, critical

Mary Brown Bullock is with the Committee on Scholarly Communication with the People's Republic of China of the National Academy of Sciences, Washington, USA.

learning from foreign sources, provided that "the role of the professional contingent in the field of science and technology" is brought into full play. He lists four basic areas for improvement: data compilation, scientific instruments, quantification and standardisation, and scientific and technical publications.

The title of the second article, 'Bear in mind Chairman Mao's concern for and teaching on education in science and technology', is almost self-explanatory. Written by Chou P'ei-yuan, vice-chairman of the Chinese Scientific and Technical Association, it cites Mao Tse-tung repeatedly in affirming the importance of theoretical research in the natural sciences and the need to up-grade China's major universities. Chou joins a host of other authors in invoking not only Mao, but more convincingly former Premier Chou En-lai, in legitimising this renewed emphasis upon science and technology.

### Science conference planned

Political support for Chinese science is also provided by China's present-day leadership. Chairman Hua has personally addressed a number of scientific conferences, and has called for a national conference on science and technology to be held next spring. But it is Vice-Premier Teng Hsiao-p'ing's imprimatur which is most evident.

One of the key signals that a new policy was in effect, and that Teng was about to be rehabilitated, was the official praising of Teng's 1975 'Outline report on the work of the Academy of Sciences'. Repudiated when written as a "poisonous weed" by the 'gang of four', this article urged raising research standards within the Academy's research institutes.

Not only are Teng's pragmatic concepts now flourishing, but he also appears to be following Chou En-lai's footsteps by taking a personal interest in meeting visiting American scientists, accompanied by senior Chinese scientists. These meetings, announced in the Chinese press, play an important part in enhancing the role of China's intellectuals.

It is too early to identify specific new directions in Chinese scientific and technological research. The conferences which have already been convened at both the national and provincial levels have been on a range of topics, including high energy physics, agricultural sciences, and geology. Seminars have been held on developments abroad in electronics, laser technology, and communications, fields which have featured prominently in international exchanges. As more details unfold concerning a proposed 1978 National Conference on Science and Technology, and as publications ex-

pand, additional research priorities should become evident.

It is also too early to predict how modifying China's former autarky will affect its international scientific and technical relations. It is important to realise that modest exchange between Chinese and Western scientists has been underway throughout the 1970s. For example, over thirty Chinese scientific delegations have visited the United States since 1972 under the centralised auspices of the Committee on Scholarly Communication with the People's Republic of China. Many more scientists and engineers have participated in commercially-related programmes.

Other nations have had similar experiences, and also have begun longer-term individual visits. Significant signs of a changing Chinese posture might be expected to include an increase in Chinese scholars studying abroad, the inauguration of cooperative scientific research programmes, and expanded purchases of foreign technology.

There has recently been an expansion in the numbers of scientists and engineers from all countries visiting China, and they describe a scientific renaissance. Individual Chinese scientists describe themselves as being "jubilant" over the new policies. Hosts have been eager to arrange substantive itineraries and to provide opportunities for foreign scientists to meet individually or in small discussion groups with Chinese colleagues.

During October, for example, a series of joint seminars on specific topics in cancer and astronomy are being arranged for two CSCPRC delegations. Americans hosting visiting Chinese scientists and engineers have likewise remarked on the relaxed and

candid attitude of their visitors. A new dialogue appears underway.

It is perhaps significant that leading Chinese scientists, Chou P'ei-yuan and Pei Shih-chang, were seated at the head table with US Secretary Cyrus Vance and the Chinese Foreign Minister, Huang Hua, during Vance's August trip to Peking. However, since the absence of diplomatic relations may provide some restrictions to programmes with the United States, China's interchange with Britain, Western Europe, Japan, and Australia will probably provide the first signs of major policy change. In this connection, an exchange of high level groups between the Australians and the Chinese Academy of Sciences has recently been planning seriously for longer-term programmes.

Since the beginning of this decade, the developing and industrial world has been fascinated with China's attempts to fashion a science and technology policy which includes the masses, traditional science, and indigenous technology. One need only remember the eruption of interest in the early 1970s when the rest of the world 'discovered' acupuncture and barefoot doctors.

World attention is now focusing on the more technical, professional aspects of China's new policies. Major changes in science and technology policy are certainly underway. But this new emphasis will not entirely replace the heritage of the Cultural Revolution. Chairman Mao's dictum that science should "serve the people" has been refined by Chairman Hua's "May science and technology flourish, and may the good news pour in". The latter part of that phrase, "good news pour in", however, suggests that results, now as before, are still expected. □

Chinese seismologist briefs American delegation on Hsinfeng dam, near Canton

# Mass surveys to detect cancer

**Eleanor Lawrence**, who talked to an American scientist recently returned from China, reports on the particular interest China holds for the cancer epidemiologist

A GROUP of cancer specialists was among the first medical teams from the United States to visit China in the more relaxed atmosphere following the fall from power of 'the gang of four'. And according to one of the team, Dr Robert W. Miller, Chief of the Clinical Epidemiology Branch of the US National Cancer Institute, China turned out to be an aetiological wonderland for the cancer epidemiologist. In particular, the causes of several cancers, unusually common in certain regions of China are becoming amenable to study. The clues come from parallel incidences of similar cancers in domestic animals in the epidemic areas. The parallels have come to light over the past decade as a result of mass surveys. The patterns of incidence strongly suggest environmental causes for these cancers and this is the aspect the Chinese appear to be tackling most vigorously.

Mass surveys and screening, largely carried out by the barefoot doctors and local people, are the most important and most emphasised aspect of China's fight against cancer. The emphasis is on identifying high risk areas, early diagnosis and treatment, and prevention by health education. Where early diagnosis coupled with simple surgery is likely to be successful, as for oesophageal cancer, it is widely practised in the country hospitals and the success rate is high. Radiotherapy and sophisticated chemotherapy is available in hospitals in the large cities but Dr Wu Huanhsing, head of the Oncological Hospital of the Chinese Academy of Sciences in Peking believes that "you can't treat cancer with a big machine".

Dr Li Ping, Deputy Director of the Cancer Research Institute in Peking, showed the American team the first results of a massive survey of cancer mortality, which eventually will cover all of China. Deaths from the commoner types of cancer are recorded commune by commune (each commune consists of about 8,000-10,000 people) and maps made of the relative incidence of each type of cancer within a province. Of the 29 provinces in China, one has already been completely mapped and six more are in preparation. Already sharply-defined areas of high incidence of liver cancer, for

example in southern China, can be seen, whereas lung cancer deaths are distributed non-randomly (as in similar maps prepared in the United States by the National Cancer Institute). Writing in the English language magazine *China Reconstructs* (October 1977) Dr Li estimates that a million barefoot doctors are engaged in the survey.

## Mapping high incidence areas

The Chinese have set up some 30 bases for cancer study, prevention and treatment in villages, factories and mining areas throughout China, in areas with high incidences of cancer. The clearest picture so far of cause and effect has been obtained for oesophageal cancer, which has an unusually high incidence in some regions of northern China, focused on Linhsien county. Among the 700,000 people in the county one new case of oesophageal cancer is diagnosed every 8 hours, some 50 times the rate for US whites.

The high incidence of human oesophageal cancer is paralleled by a similar excess of gullet cancer in domestic chickens in the area, leading to the suspicion that both cancers might have a similar environmental cause. Important clues to the possible cause have been uncovered by the Chinese following the relocation of more than 50,000 people from Linhsien county to Changshun county, 350 miles away, where the incidence of oesophageal cancer is low. When the people moved, in 1967-68, to allow a new reservoir to be built, they apparently did not take any of their

chickens with them but bought new birds when they arrived in Chungshan, from flocks hitherto free of gullet cancer. Since then, however, 12 chickens of the 5,500 owned by the immigrants have developed gullet cancer although no cases have been reported in about 2,400 chickens belonging to the native population. This pointed to a carcinogen limited to the chicken's immediate environment, but not apparently confined to Linhsien county. One suspect may be a pickled vegetable mix, a speciality of Linhsien, which could also be fed to the chickens in table scraps. Nitrosamines have been found in this mix and the American team has brought back samples, which will be tested in the Ames test amongst others, for mutagens which may also be carcinogenic.

The American team commented that changing the chicken food from table scraps to grain would provide an unambiguous answer to whether the carcinogen was in food eaten by both chickens and people. The Chinese are indeed mounting a campaign in Linhsien county itself which is aimed at: preventing food and grain from moulding (toxins produced by some mould contaminants are suspected carcinogens), correcting a molybdenum deficiency in the soil, removing excess nitrates and nitrites from water and "changing undesirable dietary habits" —presumably to eliminate food containing nitrosamines. They are also now able to detect oesophageal cancer in its earliest stages by mass screening and the cure rate, by surgery, is apparently very good.

## Pinpointing several causes

According to Dr Miller the Chinese are not so interested in pinpointing a specific cause, as in preventing cancer by controlling a range of possible causes. They believe that there is no one specific cause for any type of cancer and that at least four factors will be involved. This perhaps accounts in part for the resistance the American team found to the idea that lung cancer is overwhelmingly caused by cigarette smoking. A substantial proportion of the population in China now smokes and the lung cancer rate is also increasing, although because cigarette smoking only became widespread in China some 20 years ago the full impact has not yet been felt.

Another cancer which has an unusual incidence in China and which also seems to be associated with a similar cancer in domestic animals is nasopharyngeal carcinoma, which seems to cluster in southern China. In a rural area 100 miles from Canton, the American team talked to a barefoot doctor who told them that six people

Storage jars for clean, uncontaminated grain.

This visit was sponsored by the National Academy of Sciences Committee on Scholarly Communication with the People's Republic of China.

in the 3,000 under his care had developed the tumour in the past decade. Only when they returned to Canton did the American scientists find that nasopharyngeal cancer had been found to cluster in pigs elsewhere in Kwangtung Province—the 'snuffling pig' syndrome. As with the chickens, this could point to a carcinogen limited to the immediate environment of the pig, a much more restricted environment than that of humans and easier to

analyse.

Hepatocellular cancer (liver cancer) is 'epidemic' throughout southern China and the Chinese are looking at hepatocellular cancer and cirrhosis in domestic ducks, although no systematic survey has apparently been made. Studies on the inherited susceptibility to various types of cancer are not apparently given great prominence in China, prevention and early detection and treatment being stressed. But the

American team obtained anecdotal evidence of several instances of very strong familial clustering possibly indicating genetic susceptibility.

The American team also included pathologists, pharmacologists and clinicians and a full report of the visit will be published next year by the National Academy of Sciences. In the present climate of a free exchange of information, it should be one of the largest reports yet. □

## Two major controversies

**T. B. Tang** traces recent changes in China's education policy and the status of her scientists

**F**OLLOWING the death of Chairman Mao and before the 'gang of four' fell from power, the two major controversies in China concerned cultural activities and the educational system. It was in these spheres that the 'gang' exerted influence for the longest period of time, and it is therefore not surprising that these fields are now seeing the largest and most definite changes, with important implications for the development of science and technology.

One early indication of this was the widely-publicised memorial meeting held for Chou Jung-hsin in August. Chou, who died last year, was a former Minister of Education, and had previously held a leading post in the Academia Sinica; it was disclosed that he had been "framed" by the 'gang', and had suffered considerably as a result. An article by the Ministry of Education in the current issue of *Red Flag* now asserts that the educational policies in force during the 17 years before the Cultural Revolution were basically correct. It implies that the "Sixty-Point Document on Higher Education" prepared by the Ministry in 1961, could still be relevant today.

Recent events indicate increased concern over higher education in science and technology. National conferences were held in September on compiling university text-books and, more crucially, on university enrolment. A new periodical, *People's Education*, also started publication in October to serve as a forum for discussing changes in education policy.

One of those changes affects applicants for university places. They are now to take the initiative in putting forward their own names for consideration rather than waiting for selection. Although the universities will continue the "open door" policy of enrolling workers, peasants, demobilised soldiers, and ex-students settled in the countryside, a policy of "walking on two legs" is to be followed, so that direct entry from middle schools is now allowed, and is in fact scheduled to account for about 30% of available places.

In the universities, administrative responsibilities will be delegated by Party branch committees to principals and faculty and department heads, posts which had previously been abolished, but now are being re-introduced ('revolutionary committees'

will be phased out). Entrance examinations which "are necessary in evaluating the political and general educational level of entrants", will also return, being held annually in July or August.

Political education, however, will not be played down; most university students, for example, are likely to spend one month every year living and working with workers or peasants. China continues to encourage expansion of the 'July 21' workers colleges run by factories and mines, and agricultural institutes modelled on the 'Chao Yang' college. They accept peasant-students selected by communes who return there immediately after graduation.

### Enrolling research students

It is repeatedly stressed that "to achieve big progress in science and technology it is imperative to arouse the masses boldly"; but, for science at least, more importance appears now to be attached to "the backbone role of professional scientists". The teaching curricula of many universities are being revised, and much effort is being spent on bringing textbooks up to date.

Universities are apparently intended to serve as centres of both higher education and research. Together with institutes under the Academia Sinica, they are preparing to enroll research students for the first time in ten years. Applications will be received this year until the end of December, and post-graduate training is planned to last three years. 1977 graduates will be allowed to take a proportion of the allocated places.

Young people in China are increasingly urged to devote themselves to science. In the rationalist tradition of Marxism, socialist man is substantially equated with scientific man; an additional persuasion now is the call of the four "modernisations", namely agriculture, industry, defence and, most importantly, science and technology.

In November a science week in Shanghai was attended by over two

*T. B. Tang is at St John's College, Cambridge.*

Sueu

million school students. And many leading scientists participated in a meeting of the Chinese Scientific and Technical Association in Peking in August, which was attended by over seven thousand middle school students and teachers of mathematics, physics, and chemistry. Delegates were exhorted to "acquire knowledge to scale new heights in science and our socialist motherland". In a typically Chinese manner, the biologist and popular science writer Kao Shih-Chi composed a poem for the students entitled "Make Science and Technology Serve Our Motherland".

The latest drives in China's educational front are no doubt directed towards economic ends; but they also have political goals. The persistent incentive is not materialistic—though such an aspect exists—but ideological, relying on popular enthusiasm.

This brings us to the position of scientists. The attitude towards professionals and scholars has varied widely in recent times. Up to 1956, intellectuals were allowed to retain the status and privileges traditionally reserved for scholars in China as long as they modified their views to fit the current political mood. From 1960 up to the Cultural Revolution certain Party leaders conceded that academics and specialists were useful whatever their personal ambitions or political consciousness.

After the Cultural Revolution and the advent of the 'gang of four' the policy changed. Intellectuals were considered to be entirely dispensable unless they were "red", which meant usually that they had not been "contaminated" with "bourgeois" ideas abroad, that they had not shown "individualism" by producing scholarly works, and that they were not in prominent positions and earning high wages.

#### Working hard for socialism

Today, according to the *Political Report*, "the overwhelming majority" of intellectuals "are willing to work

hard for socialism and are indeed doing so". Political apathy will not be allowed, and help and encouragement will continue to be given to intellectuals "to remould their world outlook"; at the same time, however, they will be guaranteed the conditions to put their abilities to good use.

The "Circular on the holding of an All-Nation Conference on Science", issued in September, announced the restoration of titles for technical personnel as a means of enhancing their sense of responsibility. The Academia Sinica, for example, now has research assistants, and assistant, associate, and full research fellows. An increase in wages took place at the beginning of October, with scientists—among others—given priority for individual recommendation.

The *Political Report* states that one of the aims of the forthcoming All-Nation Conference is to "commend the pace-setters, especially those scientists and technicians as well as workers, peasants and soldiers who have inventions and innovations to their credit". The practice of awarding orders and decorations to scientists, first introduced in 1956, may also be restored.

The *Political Report* also suggests that the Chinese people should unite with "our countrymen overseas"; it appears that a State Department for Overseas Chinese Affairs may soon be formally set up. The main contribution of ex-patriate Chinese, of which there are about 20 million, will be to act as bridges of friendship; but in particular cases they can do more.

This year, for example, has already seen the visit of C. S. Wu and the three American-Chinese Nobel prizewinners in physics. For Yang Chen-ning it was his seventh trip, and in the last few visits he has collaborated on important research projects. Another collaborative research project by Chinese scientists at home and overseas is the research on the heredity role of cytoplasmic mRNA, in which M. C. Liu and P. Y. Pang from Temple

University took part.

#### International collaboration

Perhaps significantly, the *People's Daily* published on 3 October a poem entitled "A returned scientist". But whether any overseas intellectual wishing to return to China, either short-term, long-term, or permanently, is able to do so remains essentially a political decision.

The international transfer of science and technology takes many forms. The most obvious ones are importing instruments, machinery, and complete plants, and acquiring information through the circulation of journals and reports, and through private communication. But this transfer also takes the form of international movements by scientists and engineers.

Many in the West will have, through direct or indirect contact, felt the expanding number of exchange visits with China. In addition, we have been given to understand that, at least for Chungshan University (situated in Canton and one of the 28 "key universities"), visiting professors may soon be welcomed, particularly from the Second World. And here the consideration will be mainly academic.

Chungshan University has announced that it is arranging joint research projects with the Polytechnic of Hong Kong. This collaboration may be viewed primarily as a social relations exercise, but it is an important step.

Another development, reflecting the emergent liveliness in Chinese scientific circles, is the recent appearance in *Acta Astr. Sinica* of a paper contending that the universe is closed. Apparently contradicting the Marxist dictum that the universe is not only boundless but also infinite, the paper might well have been refused publication, a few years ago.

Recently, there have been many changes in China's science and education policy. Most—if not all—are not reversals of previous ideas, but a renewed emphasis on policies formulated in the era of Chairman Mao. The changes are necessary not only to repudiate the manoeuvres of a group now fallen from power, but also to prepare China for the conditions she is likely to face in the near future.

In developing her science and technology, China as a Third World country has had 28 years of useful experience which constitutes a basis on which she can fruitfully draw for future programmes. She is endeavouring to develop a modern technological society modelled neither on Western countries nor on Russia and is taking a path never previously followed. In China as in the West, however, there are many problems ahead, not the least being the social impact of progress in science and technology. □

# Looking to the stars

**Professor Graham Smith, the British astronomer, visited China this autumn and returned feeling China needs a large injection of Western expertise**

ANY scientist must be encouraged to hear that his government is in favour of a rapid expansion of his subject, and that adequate resources will become available. It must, however, be a daunting prospect when excellence is required within a few years, especially when a lack of contact with contemporary science, and a long history of neglect and social turmoil, provide a starting point far behind the world's front runners.

The training of astronomers in China has suffered in recent years alongside all areas of university education. Nevertheless astronomy, and especially radio astronomy, is a well favoured subject in contemporary Chinese science. There is both a determination to achieve excellence in at least a handful of research fields, and an unprecedented encouragement of contacts with the West.

On my visit to China in October as representative of the Royal Greenwich Observatory, I was accompanied by Professor Wynne, who was particularly interested in optical design. We therefore not only visited the major observatories but also the major optical institutes and factories, in most of which Wynne's work on computer optimisation of lens design was being adopted.

The main observatories in China are at Shanghai, Nanking, Peking and Kunming. Shanghai Observatory is mainly concerned with measuring time through the use of transit telescopes and astrolabes. It has an astrolabe of novel and advanced design, recently described in *Acta Sinica Astronomica* (an English translation of this journal is now available). Although Shanghai is a centre for the time service in China, it has no caesium clocks, and China takes no part in international efforts to maintain the Atomic Time Scale.

Nanking has the famous Purple Mountain Observatory, where some of the most spectacular of the fifteenth-century bronze instruments are preserved, and some astrophysical work and satellite tracking observations are now carried out. Peking Observatory has several departments, notably the optical observatory at Hsin Lun, 960 m above sea level and 110 km NW of Peking, where there are several working telescopes, including a 60 cm Cassegrain recently built at the Astronomical Optical Factory of Nanking. The same factory is now undertaking the construction of a 216 cm telescope

for Hsin Lun.

The radio observatory of Peking is at Mi Yun, about the same distance from Peking. The site is well chosen on a flat plain screened by hills from interference, and has a 1 km array of 9 m reflectors. And at Kunming, in the south-west of China in Yunnan province, there are solar and astrometric telescopes, and an active observatory which recently started a large expansion.

Peking University has no research school in astronomy, even though radio astronomers are taught there. Their training has consisted of a third undergraduate year in radio astronomy, in which practical experience with a very elementary solar radio telescope played an important, but hardly advanced, rôle. The modern techniques of aperture synthesis and very long baseline interferometry (VLBI) were often mentioned, but there is naturally no direct experience of such important ingredients of modern radio astronomy, and no plans have yet been formulated of how to start.

The radio observatory at Mi Yun is the obvious nucleus for any expansion in the subject. The 22 paraboloids of the 1 km array have recently been rebuilt, increasing their diameters from 6 m to 9 m, and are used as a phased array at frequencies of 450 MHz and 176 MHz, observing the sun. The angular resolution is to be increased by the addition of further paraboloids, spaced at further intervals of 1 km, and used in a switched system.

The next development planned would be to rebuild the whole system for use in aperture synthesis, although this would be a very large task, involving amplifiers and separate cables for each paraboloid, a new complex receiver system considerably more sophisticated than the present simple switching receiver, and an on-line computer.

My own view is that rapid progress of the necessary order could only be achieved by a determined infusion of ideas and techniques from the world's large radio observatories. The problem of language is serious, since few visitors could even hope to learn Chinese, and surprisingly few of the Chinese astronomers speak English well. The main problem, however, is the lack of students and young research workers with any familiarity with modern work. It is essential for some of the best of young Chinese astronomers to spend considerable periods abroad; possibly two years in a major observatory would

*Fifteenth century astrolabe at Purple Mountain Observatory*

be needed.

Although radio astronomy is at present the favoured subject, progress might be better made by concentrating on optical, or possibly on millimetre wave astronomy. The site of the Peking optical observatory is not particularly good, although it may be the best within reasonable distance of Peking. But there must be some very good sites in China, especially at the high altitude which millimetre wave astronomy demands.

Kunming itself is at 2,000 m, and the skies are clear, while not far from the city are mountains over 2,500 m which might provide good sites. There is undoubtedly a wealth of good astronomy to be done with moderate sized optical telescopes; the worrying aspect of radio astronomy is that middle-sized radio telescopes may be no use in comparison with the giant arrays now being used, or constructed, in a few major observatories.

In the observatories and institutes which we visited there are plenty of people, and there are new buildings which at Kunming reach a lavish scale. There must be room for a staff of at least 500 when the buildings are complete even though the observational work in progress at present would occupy a staff of only about 50 at an established observatory. Optical design is becoming well understood in China, and the techniques of optical working now extend to the figuring of mirrors up to 2.5 m in diameter.

Instrumental design has been well demonstrated in the new astrolabe constructed in Nanking and used in Shanghai and Kunming. Spectrograph design needs study, but gratings are now available which are ruled at Chang-Chun, in northern China. Low expansion glass is now made in Shanghai, although only in pieces up

to 1 m in diameter. (The 216 cm mirror is a piece of pyrex made in Russia, and presumably imported almost 20 years ago.)

There is much enthusiasm and a good-will towards astronomers which is refreshing and helps to make a visit to China an extremely pleasant occasion. The Chinese want to make real

advances, and recognise that to do so they must participate in the international exchange of ideas which is an outstanding characteristic of astronomy.

It would be very helpful to China's scientists—and surely very good for international good will—if astronomers were sent abroad for extended periods

of study. The regeneration of Chinese science without such contacts will otherwise be a slow and uncertain process. Whether it occurs in radio or in other branches of astronomy will only emerge later, when there are sufficient trained young astronomers able to make their own educated choice. □

## Divide between Peking and Taipei rules out scientific cooperation

*The issue of the two Chinas is gradually concerning more scientists as the Peking government seeks membership in the international unions at the expense of Taiwan. Richard Harris, of The Times, who lived in China before and after the Communist government came to power, describes the historical background and explains why a two-China policy is unacceptable to either government.*

IN 1895 China was ignominiously defeated in a brief war with Japan over Chinese suzerainty in Korea, and as a result Taiwan had to be ceded. China felt this defeat by Japan much more shameful than either of the earlier Anglo-Chinese wars in the nineteenth century. Moreover, emotions were stronger in 1895 since by then a slow response to western intrusion had evoked a nationalism never before felt in China.

The two decades following that defeat (which included the actual fall of the Ching dynasty in 1911) brought home to the Chinese the need for their twentieth-century revolution, and defined its objectives. These involved the regeneration of China—the Chinese term used for revolution has this meaning—so that it would again be united, independent and strong.

United meant the return to the sovereignty of one government over all territories from which such sovereignty had been lost by China from 1840 onwards. Independent meant the abolition of any privileges otherwise acquired by foreigners—such as the treaty ports and the customs control exercised in accordance with “unequal” treaties. Strong meant a China militarily and industrially the equal (if not the superior) of any country in the advanced western world.

Ever since 1895 the loss of Taiwan has remained indelibly in the Chinese mind as a shame to be expunged. Along with other causes for shame, the emotions of Chinese nationalism survived unappeased in this century until

the first government strong enough to pursue the national objectives emerged in 1949. As the communist armies moved southwards in that year, all patriotic Chinese welcomed the end of foreign privilege, and foresaw that Chiang Kai-shek's retreat to Taiwan could only be temporary since all his support had gone and his troops were demoralised.

Suddenly, however, in quite unforeseen circumstances, hopes of a united and independent China were dashed with the outbreak of warfare in Korea (not of China's making), and President Truman's decision to place American power between Taiwan and the intended assault on it from the mainland.

Unlike the situation with East and West Germany, the incoming revolutionary government of 1949 therefore found itself facing exactly the same circumstances as earlier new dynasties when pockets of support for the defeated dynasty were still resisting. Such redoubts of resistance had always maintained their own legitimacy; by so doing they challenged the legitimacy of the incoming rulers in Peking.

Moreover those who thought they had seen the end of foreign privilege and foreign interference in the affairs of China now saw just such foreign interference reasserted in favour of Chiang Kai-shek. An American security treaty soon assured the island against attack, while American hostility to the People's Republic for 20 years impeded diplomatic recognition, and the occupation of the Chinese seat in the UN by the Peking government, which was retained for the government in Taiwan.

As seen from the west, much has changed since 1950. Taiwan's economy has shared in the growth area dominated by Japan. The circumstances of the Korean War have been forgotten. Why should Taiwan be “handed over” to the communists, it is asked. Furthermore, now that the United States has changed its policy of containment towards China; and has established a

mission in Peking, why should China not agree to American requests that the government in Peking should renounce any intention of occupying Taiwan by force?

No one with any first hand experience of Chinese nationalism, or knowledge of Chinese history, could expect the Chinese to meet such demands. Consider them in reverse: would the Americans, solely at China's request, be prepared to renounce action of some kind about territory that was part of the United States?

Another argument offered by westerners is to use the German analogy, and to ask why Peking should not be content to allow Taiwan a comfortable independence. Those who suggest this, however, do not realise that the government of the Kuomintang Party in Taiwan shares all the attitudes of the government in Peking. Each government claims to be the government of China; once the government in Taiwan renounced that claim, it would lose its *raison d'être* even if its reconquest of the mainland is an absurd ritual declamation.

Whatever the arguments, there is no possibility that action by the west, by the UN, or by any other outsider can determine the future of this question. And of those who cling to the hope that the “Taiwanese”—who certainly do not like the dominance of Kuomintang mainlanders, and who find that dominance has not been much mitigated by the greater association of Taiwanese in government in recent years—will assert their wish for independence, one can only ask whether the record of Chinese history gives them any support at all.

Foreign intruders have ruled parts of China at many times, and all of it in the case of the Mongols and Manchus (Ching). But at no point has the concept of unitary government for all persons who are Chinese ever been questioned—not even by the warloads of the twenties. Supporters of a “two-China theory” have been, are and always will be anathema to the government in Peking.

This should explain why neither government will entertain any contact with the other, and why the battle between them in all international organisations, from the UN downwards, will allow no co-existence. □

## Israeli scientists woo Egypt

AMONG the documents that Egyptian President Anwar Sadat took back with him to Cairo after his recent extraordinary visit to Israel was a list of 36 international scientific conferences due to take place in Israel this year. Appended to that list was a request that Sadat facilitate the participation of Egyptian scientists in each of these conferences.

A much more far-reaching proposal for scientific cooperation was made immediately after Sadat's departure by Technion Professor Josef Rom, an aeronautical engineer now serving as a Likud member of the Knesset. Rom said that the current Israeli-Egyptian political dialogue should be accompanied by concrete measures to foster joint programmes in as many spheres as possible, among them science and technology. "For example," Professor Rom declared, "we must begin to plan and if possible to carry out bi-national projects such as the construction of atomic power stations and desalination plants in Sinai".

Such a scheme, in fact, was proposed many years ago by Dwight D. Eisenhower, and endorsed by other American leaders, all of whom thought it could help bring peace to the Middle East. Only later did it become clear that in the absence of peace, co-operative development projects were simply not feasible.

But before that scheme was finally shelved, American, Israeli and Egyptian scientists had come together at the Oak Ridge National Laboratory, then headed by Dr Alvin Weinberg, to work out details of how it could be carried out. They envisaged the installation of

two reactors with a combined output of 1,000 MW in the El Arish area, south of the Gaza Strip. The power generated was to be used by newly established industries producing chemicals, fertilisers, plastics, and aluminium, as well as for the operation of a plant to desalinate 1,000 million gallons per day of seawater—enough to irrigate some 300,000 acres of land in the deserts of Sinai and the neighbouring Negev. It was assumed that this American-financed programme would bring great material benefits to both Israel and Egypt and also provide employment opportunities for Arab refugees in the Gaza Strip.

In the interval most of these refugees have obtained jobs in Israel and many other things have changed. But Dr Gerald Stanhill, an Israeli scientist who helped work out some of the agricultural aspects of the scheme, hopes that it will be revived in one form or another.

At the same time, Dr Stanhill warns against the dangers of prematurely promoting "intensive, California-style agriculture" in a country like Egypt because this would involve an enormous investment in money and trained manpower as well as flooding Egypt's already overcrowded cities with "fellahs" who would lose their jobs in the countryside and fail to find new ones in the cities.

But quite independent of the Sadat visit, Stanhill and his colleagues at the Volcani Centre of Agricultural Research have been considering how low-technology irrigation techniques similar to those used on Israeli moshavim (smallholders' settlements) could be

introduced into the Egyptian countryside in a way that would substantially improve living standards without destroying the existing fabric of society. And these techniques—together with those from dozens of other countries—are being brought to the attention of the world's farmers and researchers through the efforts of the International Irrigation Information Centre (IIIC) located at Volcani.

Even so, personal contact is bound to be a more effective means of communication. This can be seen in the Gaza Strip, controlled by Israel since 1967. There Egyptian-trained agricultural instructors were taught Israeli techniques in irrigation and other spheres, and then brought them to local farmers. As a result, average annual production in agriculture has grown by 25.4% (as compared to 6–7% in Israel), while income per farmer has risen from \$130 to \$732.

There is enormous enthusiasm among Israeli researchers—be they working in agriculture, medicine, electronics or geophysics—to establish close contacts with their counterparts in Egypt, by far the largest and most developed scientific centre in the Arab world.

Weizmann Institute President Michael Sela was undoubtedly speaking for many others when he said this week that the Institute "soon hoped to have visiting scientists not only from Berkeley, London, Paris, and Tokyo, but also from Cairo and Alexandria". "Moreover," Professor Sela added, "if our researchers can spend their sabbaticals on the banks of the Thames or the Seine, there is no reason why they shouldn't be spending them on the banks of the Nile".

**Nechemia Myers**

## Euratom burns its public relations' fingers

RELATIONS between the European Commission and the environmentalist lobby got off to a bad start on the first day of last week's public hearings into nuclear energy with the publication of a report purporting to show that the European Atomic Energy Community (EURATOM) was planning a propaganda campaign to sway public opinion in favour of nuclear energy.

The "evidence" for this claim was a report "Design of a Task Force to Build Public Awareness and Support for Nuclear Power", prepared under a Euratom study contract, which was produced at press conferences held simultaneously in Brussels and Rome by the Italian Radical Party and anti-nuclear lobby.

The report, prepared by Alessandra Ovi of the Nuclear Engineering De-

partment at the Polytechnic Institute of Milan, and written in November 1976, described the details of a communication process which would "successfully tackle" public opposition to nuclear power.

Techniques suggested for achieving this included making use of the "authority and credibility" of senior members of the medical hierarchy to diffuse a pro-nuclear message. The report recommends setting up a task force of experts who would "design adequate messages" to provide a coordinated response to nuclear opponents.

The commission's first response to the Italians' charge of manipulating public opinion was to dismiss the document as a "forgery". Later, however, when copies of the document

were produced bearing the EURATOM Study Contract Number 605-76-03, the commission admitted its authenticity.

But according to the commission, the document bore no relation to official policy. It had apparently been a sub-contract made under a much larger contract (to which the contract number referred) on the general assessment of nuclear risk.

The report had been immediately disowned by EURATOM when its existence had become known in June of this year, with firm instructions that the line of inquiry it indicated should not be pursued further. How it got into the hands of the Italian environmentalists is not known; but its very existence, and the swift reaction which it aroused from the commission, was sufficient to add an initial jarring note to the three-day hearing.

**David Dickson**

## New broom at the DHSS

**E**FFORTS to streamline the administration of medical research have been promised by the new chief scientist at the UK Department of Health and Social Security, Professor Arthur Buller.

The promise is likely to be widely welcomed by Britain's medical science community. There has been growing frustration in recent months at the burdens imposed on research by the implementation of Lord Rothschild's proposals for research council funding.

Professor Buller brings to the job a growing awareness that the Medical Research Council (MRC) and the DHSS must work closely together, and with mutual trust, if the new system is to be made to work. Only this, for example, will avoid the DHSS presenting the research council with requests—such as a “cure for schizophrenia”—that are impossible to meet at the present time.

A close liaison will also, Professor Buller feels, avoid a repetition of the situation that arose two years ago when the Government's economic problems led to hastily imposed cutbacks of department research budgets, and consequently a reduction of £900,000 in the money available to the MRC from the DHSS.

“It is impossible to maintain any type of meaningful relationship between the two bodies if this type of thing, which happens when administration gets quite separated from research, is liable to take place. From the MRC's point of view, last time was a near disaster.”

Professor Buller, whose appointment was announced last week, will take up his new position with responsibility for a £28m research budget from the beginning of January. He is keen to reduce the extra administration that the Rothschild proposals have involved, a desire he shares with the new secretary of the Medical Research Council, Professor James Gowans.

Unlike many scientists, however, he does not criticise the philosophy behind the proposals, under which about 25% of the MRC's £52m research budget is now allocated by the department to the research council on a “customer-contractor” basis.

According to Professor Buller, the problem lies in the way that this has been done. “In the past, too much of a meal has been made of being seen to implement Rothschild. An enormous exercise, which has been expensive and time-consuming for both scientists and administrators, has been mounted so that both sides could demonstrate that they were carrying out Rothschild's recommendations”, he says.

By cutting down on this type of activity, while concentrating on what remains necessary to maintain an effective partnership between the MRC and the DHSS, Professor Buller hopes to simplify the administrative system between the two bodies, without any loss of effectiveness. And it is a goal which, he claims, is already shared by the DHSS.

Professor Buller has been seconded to the department from the University of Bristol, at which he is professor of physiology and dean of the faculty of medicine. He shares a general reputation claimed by the university for pragmatism rather than politics in administrative affairs, although membership of the non-academic staff salaries committee has made him no stranger to the latter.

Buller gained further experience in the world of medical politics at the MRC itself, where he is at present chairman of the neurobiology and mental health board and a council member. The board's main concern in recent years can, he says, be succinctly summarised: “We have spent our time trying to live with Rothschild”.

One of Buller's aims likely to receive widespread support among scientists is his desire to return the initiative on research back to the research worker. The most important thing, he stresses, in avoiding the waste of money is to get good scientists doing research, and then

*Arthur Buller, new chief scientist*

to a certain extent to follow their judgements.

The real need is not the development of ways of directing research from outside, but the successful application of its findings. “We need to keep a very sharp eye on ways in which the research being done by scientists in ivory towers can be exploited for the improvement of health care”, he says.

“In the past a number of important discoveries have lain fallow and not been exploited. Penicillin is an example where a failure to pick up the possibilities early enough meant that the industrial lead was given to the US. I am very keen to avoid this type of thing in the future”.

**David Dickson**

## Indian science reorganised

**T**HE Indian government has now issued a list of the 17 laboratories that it intends to detach from their present position with the Council of Scientific and Industrial Research (CSIR) and relocate within user ministries (10 November, page 89). They are: ten research associations (to Industry), three museums (to Education), the Indian Institute of Petroleum (to Petroleum and Chemicals), the Road Research Institute (to Transport and Shipping), the Central Fuel Research Institute (to Energy) and the Building Research Institute (to Welfare and Housing).

In contrast to the earlier fears that the government would dismember CSIR and shatter morale, first reactions seem to be relief that the transfer has only affected laboratories most easily housed in a ministry. □

## Following a Maoist path

Romanian science is being systematically ruined “on the Chinese model”, according to Dr Mihai Dediú, a Romanian mathematician recently exiled with his family to Italy after his cam-

paign for genuine scientific activity.

Although throughout the Comecon block social doctrine states that science must serve the economy, in most states this is no more than a slogan; pure research continues following Brezhnev's dictum that “there is nothing more practical than a good theory”. In Romania however, following President Ceausescu's visit to China, a new trend began by which all institutes of pure research were gradually turned into what Dr Dediú describes as “little more than factories”.

Chemistry was the first to suffer—there is now no faculty of chemistry at all, only chemical engineering. The mathematics institute was destroyed in 1975 and some of the mathematicians were transferred to the Institute of Physics, some to industry. The Institute of Physics, in its turn, became the Institute of Physics and Instrument Production in autumn 1976. According to Dr Dediú, the Academy of Sciences no longer exists as a scientific forum. The whole emphasis is upon politics. Even Madame Eleana Ceausescu, the wife of the leader, has been appointed an academician although she has no scientific training.

Dr Dediu himself was involved in these changes, being employed at the Mathematics Institute at the time of its destruction. He was then transferred to the Physics Institute, but was dismissed before it was re-modelled.

**Vera Rich**

## Change into genes

Britain's House of Commons Select Committee on Science and Technology is to set up a subcommittee on genetic engineering under the chairmanship of Mr Arthur Palmer, Labour MP for Bristol North East. The members of the committee will be announced shortly, and it is expected that the subcommittee will begin public hearings—to which Ministers are likely to be invited to give evidence—early in the new year.

## Conserving energy

THE European Commission in Brussels is considering plans to set up a group within the energy directorate concerned directly with the problems of energy conservation.

The suggestion for such an initiative was made by various environmentalist groups during the public hearings on nuclear energy held in Brussels last week, the first of a series of such hearings on issues related to energy policy.

At the end of the three-day hearings, the chairman Dr Guido Brunner, who is commissioner for energy, announced that the proposal would be seriously considered by the commission, and that it was likely to be put into effect.

The hearing, which concentrated particularly on future energy requirements, saw a number of confrontations between the pro- and the anti-nuclear lobbies, with many well-worn positions being rehearsed by either side.

Putting the case for nuclear power, for example, Dr Rudolf Guck of Badenwerk AG suggested that the declining supply of fossil fuels, leading to a steady climb in prices, would make nuclear energy an increasingly-attractive economic proposition.

According to Dr John Chessire of Sussex University, however, current forecasts of future electricity demand were too high. In addition, whatever the price of uranium, fast breeder reactors would, he claimed, be uneconomic compared with thermal reactors.

Criticism of the European Commission's own energy policy as being "obsolescent" and ignoring "the real needs of society" came from Dr Peter Chapman, director of the Energy Research Group at Britain's Open University.

In a presentation that appeared to make a particular impact on Dr

## Prophet of nuclear doom

Mr Tony Benn, UK Secretary of State for Energy, appeared to enjoy last Friday's debate in the House of Commons on nuclear energy.

The debate was brought by Pontypool MP Mr Leo Abse, whose constituents, he said, live within 50 miles of "one of the largest concentrations of nuclear reactors in the world . . . eight reactors in operation . . . and two more planned".

Abse, who had been briefed by Tom Burke of Friends of the Earth, was demanding a government response to the Flowers report, which indicated the dangers of a headlong dash to dependence on nuclear power. Not mincing words, Abse raised the question "is a plutonium based economy compatible with democracy?" and addressed it with some eloquence.

Abse is not exactly pro-nuclear. He

'UNFORTUNATELY, MOST OF THE PLUTONIUM WE PRODUCE GOES TO POWER OUR SECURITY SYSTEM.'

ended "If we, avaricious for the apparently easy wealth that nuclear energy could bring, enter into a Faustian pact with a meretricious atomic destiny, we may have doomed our children or grandchildren to the loss of their liberties, if not their lives".

But that style is very much Mr Abse's. In more sober moments he took a view broadly against plutonium,

but not against nuclear energy as such. His points were cogent—as indeed are many of those raised by the Friends of the Earth. Tellingly, Benn was delighted with Abse's speech, which he thought "in a classic prophetic mould". Abse's, said Benn, was a "philosophical, penetrating, and perceptive speech, and I hope that it will be widely read and studied". Benn was at pains to point out that in matters of such difficulty it was worth listening to everyone and that "the pressures that are brought to bear are not—as is sometimes suggested—only those brought by the environmental lobby against the innocent nuclear power lobby". Benn went on "In my political life I have never known such a well-organised scientific, industrial, and technical lobby as the nuclear power lobby. It is not so much the Friends of the Earth as what Eisenhower might have called the nuclear industrial complex of which I am aware as a Minister."

With that view, one might have expected Benn to be more forthcoming on the question of an inquiry into the proposed building of a commercial prototype fast breeder reactor in the UK, the £2 billion CFBR1. Mr Peter Shore, Secretary of State for the Environment, has promised a fast breeder inquiry separate from the recent Windscale planning inquiry, which investigated the extension of reprocessing facilities at Windscale. Asked if the government had indeed committed itself to an inquiry on the fast breeder Benn said "We have not yet decided to set up the inquiry". And yet he added "We shall not reach a decision (on the CFBR1) until there has been an inquiry".

Mr Tom King asked for confirmation that the government would not take a decision on fast breeders until the inquiry, and suggested that the Minister had not even discussed the question of an inquiry with other Ministers. Is there progress towards an inquiry, he asked? Benn, apparently cornered, answered "I cannot undertake that there will be a debate . . . when we have settled the thermal reactor question I shall be better able to answer".

**Robert Walgate**

Brunner and other members of the commission present, Dr Chapman claimed that the commission's policy was at least four years behind that of the UK, and that the supply and demand forecasts which it had been putting forward were inappropriate, and of a "very low standard".

"There seems to have been no

analysis of the economics of nuclear systems and no awareness of the importance of storage and transport costs", said Dr Chapman.

The next public hearing, which will be held in Brussels on 25 January, will discuss some of the problems raised by the safety aspects of nuclear energy.

# correspondence

## What about the peace prize?

SIR,—I am not surprised that, in the normal way, the only Nobel Prizes to which you pay attention (27 October, page 744) are the prizes for physics, chemistry and physiology and medicine. This year, however, scientists have cause to take particular pleasure in the award of the Peace Prize. The 1977 Nobel Prize for peace was awarded to Amnesty International, who—as your own columns have not infrequently reported—have often been involved with helping scientists among the many prisoners of conscience for whom they work.

J. A. EADES

University of Bristol, UK

## Limited tenure

SIR,—Both the present Director of the Imperial Cancer Research Fund, Dr Michael Stoker, and his successor, Professor Walter Bodmer, are on record as believers in “the virtues of limited tenure as a means of maintaining high quality in research”. These are fine, high-sounding epithets, but what they actually mean for scientists carrying out research during short contracts is something totally different.

The majority of indigenous talent in cancer research in England is recruited at the doctoral or immediately post-doctoral levels; very often the “virtues of limited tenure” brutally mean—get out by the age of thirty, or certainly not much later. Nobody engaged in activities other than scientific research in the same institute, from the administrators to the catering staff, receive such cavalier treatment; indeed, it would be against the law. Often the PhD student or post-doctorate will feel it necessary to justify himself to his superiors by working long hours, to the detriment of his social life, if not his health. Certainly this will maintain high output, if not also “high quality in research”. In addition, the financial return compares badly with many other professions, quite apart from such incidental mishaps as the refusal of building societies to grant mortgages because an income cannot be guaranteed for the appropriate period of time. And of course the searing intellectual corrosion, the shame, the agonising losses of self-confidence and self-respect that characterise the phase of unemployment and readjustment—inevitable in

many cases—these are the price each individual has to pay for having done a highly skilled job cheaply and to the best of his ability.

It is perhaps unfair to single out the ICRF for blame in a situation in which the market for research scientists is presently glutted by talent of an exceptionally high order in virtually all scientific disciplines; in which the governing principles of employment in grant-aided research for those not medically qualified are primarily cheapness and expendability as opposed to merit or achievement. It is easy to spread an ambivalent gloss over the realities of the situation by glamorising the advantages of short-term appointments as a means of achieving academic excellence, though even this is a highly questionable thesis. Conversely, it is perniciously wrong that gifted young people, often guided into cancer research for reasons that have nothing in common with self-advancement, should be called upon to pay such a bitter and a heavy price for their altruism.

ROBERT JONES

Tübingen, West Germany

## Funding of basic research in chemical thermodynamics

SIR,—The membership of the 1977 Calorimetry Conference is deeply concerned with the continuing decrease in funding of research in chemical thermodynamics, especially thermochemistry and thermophysics, and the resultant decrease in data productivity in this field in the past several years. Examination of publications and of Calorimetry Conference programmes shows the greatest decrease to be in the areas of heat capacity measurements and of heat effects in chemical reactions (combustion calorimetry, solution calorimetry, etc.). These are the primary sources of new thermodynamic data for science and technology.

In North American universities, experimental expertise is in danger of being lost in important areas, particularly combustion calorimetry. Programmes in heat capacity calorimetry and in reaction-solution calorimetry are also suffering. Attention is called to the following points:

The production of fundamental thermophysical and thermochemical data for new materials, and for materials not previously

studied, is not now sufficient for the evaluation of new processes and applications. Many key areas are no longer being studied. These fundamental data are required for effective research and development in virtually all aspects of energy and technological materials programmes.

The precise determination of the appropriate properties of carefully selected ‘key compounds’ is important because the data provide anchor points for making critically evaluated estimates and correlations of the properties of whole classes of compounds. This allows the data base to be expanded greatly on the basis of a relatively small number of carefully chosen measurements.

Acquisition of new data of technological significance on a realistic time scale requires continuous funding to keep available the highly sophisticated equipment and manpower in laboratories necessary for energy-related measurements, in other words, to maintain capability. The initial investment that has already been made could be lost if sufficient funding is not continued.

Continued acquisition of fundamental calorimetric data has been demonstrated as an important endeavour in the solution of practical problems in many areas of science and technology. It is an economical endeavour, leading to increased efficiency in the choice of materials, the design of production facilities, energy conservation, and the selection of appropriate large-scale technology.

Fundamental thermodynamic data are also necessary for the critical testing and evaluation of theoretical advances in chemistry.

The conference urges that governmental, private, industrial, and university laboratories, in the light of the above comments, consider their anticipated needs for chemical thermodynamic information and identify the level of support required (manpower and facilities) to supply the information at a rate commensurate with the need.

Particularly where substantial funding reduction has occurred—perhaps originally as a temporary measure—consideration should be given to restoring support on a continuing basis.

Assurance of multi-year support rather than a strict year-by-year support is recommended because of the resulting economies and because the production of high quality data requires a continuity of trained and experienced experimentalists.

Yours faithfully,

CHARLES E. HOLLEY

Calorimetry Conference Committee,

## Ribosomal gene organisation in *Tetrahymena*

from Carol Klukas

THE finding of a single copy gene for rRNA in the micronucleus of the protozoan *Tetrahymena* by Yao and Gall (*Cell* **12**, 121; 1977) is the latest result of their investigation into the structure and organisation of the rRNA genes in this organism. It leads the authors to suggest that *Tetrahymena* may represent an evolutionary linkage between eukaryotes and their prokaryote-like ancestor.

*Tetrahymena*, a ciliated protozoan, contains a germinal diploid micronucleus which maintains the genetic continuity of the organism, as well as a polyploid macronucleus, which is formed after conjugation from the zygotic nucleus. The macronucleus functions as a somatic nucleus directing most of the cell's transcriptional activity during vegetative growth, but is destroyed at the end of each sexual generation. By DNA-RNA hybridisation using the 25S and 17S rRNAs of *Tetrahymena*, Yao *et al.* had previously shown that although 0.3% of the DNA in the macronucleus (which contains 23 times as much total DNA as the micronucleus) codes for rRNA (about 200 copies per haploid genome) only about 0.03% of the micronuclear DNA is rDNA (*Proc. natn. Acad. Sci. U.S.A.* **71**, 3082; 1974). Moreover, the vast majority of the rDNA in *Tetrahymena* exists as extrachromosomal pieces, about  $13 \times 10^6$  daltons, each containing two copies of the rRNA genes arranged in a palindrome (Karrer & Gall, *J. molec. Biol.* **104**, 421; 1976; Engberg *et al.* *J. molec. Biol.* **104**, 455; 1976).

Considering the micronuclear origin of the macronucleus and the 10-fold difference in the rDNA content of the two nuclei, it is reasonable to suggest that the extrachromosomal rDNA of the macronucleus arises by amplification from one or a few rDNA copies integrated into the germinal chromosomes of the micronucleus. Working

from this hypothesis, Yao and Gall have tried through their experiments to establish the molecular basis of this amplification, asking whether or not the rRNA genes are in fact integrated into the micronuclear genome and if they are, do they have the same palindromic structure as in the extrachromosomal rDNA in the macronucleus, and furthermore are there any rDNA copies integrated into the macronuclear chromosomal DNA?

To answer the first question Yao and Gall digested macronuclear and micronuclear DNA individually with restriction endonucleases. *EcoRI* cleaves *Tetrahymena* rDNA at one site yielding two classes of fragment ( $10 \times 10^6$  and  $1.6 \times 10^6$  dalton) from the extrachromosomal rDNA palindrome. Yao and Gall digested micronuclear DNA with *EcoRI* and identified the fragments containing rDNA sequences by radioactive cRNA probes. They found the  $10 \times 10^6$  and  $1.6 \times 10^6$  dalton fragments (probably as a result of unavoidable contamination with macronuclear rDNA) but also a third fragment of  $5.3 \times 10^6$  daltons. They interpret this to be derived from one end of an integrated rDNA gene together with its flanking chromosomal sequences. This fragment appeared as a band of very low intensity suggesting that a very few copies at most of this integrated structure exist in the genome, most probably only one.

By analogous restriction enzyme mapping experiments with *BamHI* and *HaeIII* Yao and Gall show that in fact the *EcoRI* digestion of the integrated gene also yields a second fragment of  $10 \times 10^6$  daltons. This was not recognised in the first instance because it comigrated in the agarose gel with the largest of the extrachromosomal rDNA. *EcoRI* digestion products which contaminated the preparation. These two  $10 \times 10^6$  dalton fragments are not identical, however. In extrachromosomal rDNA the fragment is palindromic so that digestion with additional restriction endonucleases is always symmetri-

cal. In microsomal rDNA subsequent digestion is not symmetrical, indicating that the  $10 \times 10^6$  dalton piece includes only  $5 \times 10^6$  daltons of rDNA, the other half being the piece of chromosomal DNA immediately adjacent to the integrated gene. Yao and Gall conclude that the rRNA gene integrated into the micronuclear genome of *Tetrahymena* exists as a single copy and not in the palindromic structure observed in the macronucleus nor in a tandem array.

To determine whether there are any integrated rRNA genes in the macronucleus the same digestion experiments were carried out on macronuclear chromosomal DNA as free as possible from contaminating extrachromosomal rDNA. No digestion products containing rDNA sequences (except for the bands attributable to the contaminating extrachromosomal rDNA) could be seen. Thus it is probable that no rRNA gene is integrated into the chromosomal DNA of the macronucleus.

These findings lead directly to the conclusion that the extrachromosomal rDNA palindromes of the macronucleus must be derived from the single integrated rRNA gene in the micronucleus. Yao and Gall propose a very plausible model for this synthesis and amplification assuming that there exists at the end of the integrated gene a palindromic sequence just long enough to allow branch migration to occur. This would provide a primer for the replication of the integrated rDNA sequence and the newly synthesised sequence could eventually be released from the chromosome as one folded DNA chain which could then replicate semiconservatively to generate the palindromic molecule observed in the macronucleus.

The finding of only one or a few chromosomally integrated rDNA sequences in the micronucleus of *Tetrahymena* is reminiscent of the low multiplicity of rDNA in prokaryotes and in the organelles such as mitochondria of higher eukaryotes; how-

ever, there is no other eukaryotic system in which rDNA has been found integrated in the nuclear chromosomes as a unique sequence.

But perhaps in the case of *Tetrahymena* this situation seems quite reasonable. The micro and macronuclei can be considered analogous to the germinal and somatic cells of higher eukaryotes except that, with the two nuclei occupying the same cell, the micronucleus does not have to direct the synthesis of ribosomes to support

itself. The macronucleus can supervise the household functions such as transcription and translation. Perhaps in higher eukaryotes where the somatic and germinal functions occur in separate cells it is necessary to have multiple rDNA genes integrated into the germinal chromosomes in order to achieve the rRNA synthesis needed to maintain the germinal cell. Hence, '*Tetrahymena* may represent an evolutionary linkage between eukaryotes and their procaryote-like ancestor.' □

## Electron diffraction up to date

from A. Howie

A conference on Electron Diffraction was held at Imperial College, London on 19–21 September, 1977.

FEW fields can surpass electron diffraction in illustrating the disparity in the pace of scientific revelation and the more measured tread of technological change. The fiftieth anniversary of the subject, marked by the conference, proved to be a timely occasion to discuss the recent work which has at last realised the promise held out by the initial experiments. Although the two main active branches of the subject stem directly from the original low energy reflection experiments of Davisson and Germer and the high energy transmission experiments of Thomson and Reid, progress in both cases has been dependent on major instrumental technology such as the development of electron microscopes and ultrahigh vacuum equipment. As emphasised by T. Mulvey (University of Aston) in an entertaining review of the early work, formidable problems of specimen preparation had also to be overcome.

The high energy work is now concentrated in electron microscopy which has become a key discipline both in materials science and in biology and depends (as in the Abbé theory of the optical microscope) on the transmission diffraction imaging process. The diffraction contrast method, most widely used in materials applications, does not resolve the atoms directly but can provide images of crystal defects at a resolution of 1.5 nm (with weak beam methods) and an accuracy of  $2 \times 10^{-3}$  nm in the atomic displacements. It is particularly suitable for structures like metals with small unit cells and was described by Sir Peter Hirsch (University of Oxford) who concentrated on the detailed way in which

dynamical theory can explain the observations both qualitatively and quantitatively. Improvements in electron microscope performance have stimulated considerable activity in direct lattice imaging, discussed by J. M. Cowley (University of Arizona) with reference to the study of complex oxides and related materials with large unit cells. The information about the projected structure obtained in this way is of great significance in numerous chemical and mineralogical applications as well as in biology.

Despite the activity in real space imaging, all interest in the transmission diffraction pattern itself has not been lost, particularly for the study of diffuse scattering in highly disordered materials. In addition, the use of convergent beam diffraction patterns taken from small areas of crystalline specimens using focused illumination and pursued for many years by P. Goodman and colleagues at CSIRO Melbourne, has become a much more routine technique with better vacuum and other instrumental improvements. A major contribution to the meeting by J. W. Steeds and his team (University of Bristol) showed how local information about structure, composition and lattice parameter can be conveniently obtained from convergent beam patterns taken along crystallographic zone axes. It can be predicted that this technique will be increasingly popular, particularly in the context of scanning transmission microscopes where extremely small areas can be probed.

The increasing use of zone axis orientations, previously avoided because of the large number of diffracted beams excited, was perhaps the best evidence presented of the mounting confidence in the use of high energy diffraction theory in such situations. This has followed increases in computing power and efficiency enabling features of electron microscope images

to be interpreted more and more quantitatively with various plane wave formulations of dynamical theory but has also been helped along recently by several useful tricks borrowed from molecular and solid state valence electron theory. Indeed for the band theorist, high energy diffraction theory has emerged as an exciting new two-dimensional game with a ball of variable mass whose behaviour becomes classical in the limit of tight binding.

Electrons rarely scatter only once, particularly in the low energy electron diffraction (LEED) range. The development of a successful dynamical diffraction theory has therefore been even more crucial in the recent use of LEED for detailed studies of surface structure. Probably the key here was the recognition about 1969 of the importance of inelastic scattering described by an optical potential which is now fairly well understood over the whole energy range, even if some basic questions such as the treatment of thermal diffuse scattering or the use of the Doby Waller factor in LEED may require more study. S. Y. Tong (University of Wisconsin) gave an excellent survey of the recent results on surface structures. About 80 structures have now been determined including a considerable number of gas-covered surfaces so that the stage of looking for trends and general principles has now been reached. The fit between theory and experiment, though not quite perfect, is most impressive and generates considerable confidence that the structures deduced will be confirmed when tested by other methods such as X-ray diffraction, in the case of sufficiently perfect underlying crystals, or angle-resolved Auger emission and similar techniques which lean on LEED for their interpretation. More speculative topics on which some progress was reported were the use of spin-polarised LEED and of surface resonance effects when a diffracted beam is parallel to the surface.

Surface structure can also be studied by reflection high energy electron diffraction (RHEED) at glancing angles. J. B. Pendry (Daresbury Laboratory) described efforts to extend LEED theory to this case using the 'chain method' where scattering from atomic rows is treated as a cylindrical problem. The ultimate advantage of electron diffraction over X-ray diffraction, the ability to form real space images, can be pressed home much more easily at these energies, particularly using scanning electron microscopy. It looks probable, therefore, that yet another development in instrumental technology will eventually allow electron diffraction to extend its steady progress to the detailed study of real surfaces. □

## Energetics and antibiotic uptake

from J. R. Saunders and  
Venetia A. Saunders

ALTHOUGH the modes of action of most antibiotics are well established, much less is known of the processes by which such drugs are taken up by bacteria. In a recent paper (*Antimicrobial Agents Chemother.* **12**, 163; 1977) Bryan and Van Den Elzen propose a mechanism to explain the transport of one particular group of antibiotics, the aminoglycosides.

The accumulation of streptomycin (or gentamicin) by bacteria can be divided into three phases. The initial phase is energy-independent and apparently involves ionic interaction of drug molecules with the bacterial surface. This is followed by an energy-dependent phase (EDP-I), which occurs before inhibition of protein synthesis by the antibiotic. In cells that are sensitive to streptomycin, but not those that are ribosomally resistant, this is followed by a third phase (EDP-II) which is also energy-requiring. This phase marks the onset of inhibition of protein synthesis and loss of cell viability and is characterised by a higher rate of streptomycin accumulation than EDP-I.

Bryan and Van Den Elzen have found that mutant strains of *Escherichia coli* deficient in haem production, ubiquinone production or active transport mechanisms accumulate less streptomycin or gentamicin than corresponding parental strains. In addition, such mutants show increased resistance to those and most other aminoglycosides. But they exhibit an increased susceptibility to the aminocyclitol antibiotic spectinomycin. This corresponds quite well with the fact that this drug is more effective than the aminoglycosides against anaerobic bacteria. Increased uptake of radioactive streptomycin was observed in a mutant that is unable to couple oxidative phosphorylation to electron transport (Unc<sup>-</sup>) and is also found defective in membrane-bound ATPase. It is interesting that this strain is hypersensitive not only to aminoglycosides but also to spectinomycin.

If streptomycin is transported into bacteria by means of a specific carrier system then compounds of closely related structure might be expected to compete with it. This is apparently not the case, but accumulation of

## How many species?

from A. Hallam

A LIVELY controversy has grown up among palaeontologists in recent years about whether marine invertebrate species numbers, or richness, increased systematically through the Phanerozoic or whether an equilibrium situation has existed, with the apparent increase through time being an artefact. The leading advocate of the first view is J. W. Valentine, who has argued for an order of magnitude increase from the early Palaeozoic to the late Cainozoic, while the steady state alternative has been propounded principally by D. M. Raup.

Raup (*Paleobiology* **2**, 289; 1976) estimated the number of species described for each of the geological periods by tabulating new species reported in the *Zoological Record*, and established a strong correlation between apparent species numbers and the present areal distribution of rocks per system. Now Sheehan (*Paleobiology* **3**, 325; 1977) has come up with another interesting finding, having made a study of those palaeontologists expressing interest in fossils of particular systems, using data from the *Directory of Palaeontologists of the World*. It turns out that there is an excellent correlation ( $r = 0.94$ ) between the number of carefully defined 'palaeontologist interest units' and the number of described species per geological period. Sheehan concludes that the total numbers of described species do not seem to reflect meaningful estimates of the original diversity.

In his reply to Sheehan, Raup acknowledges the good correlation established between the number of species described and the number of interested palaeontologists, as well as outcrop area, but maintains that nothing very positive can be inferred

from this. He prefers the view, though he cannot prove it, that geological systems with more available rock have more species and hence more species are described. In other words most palaeontologists are attracted to the most fossiliferous rocks!

Is there any way out of this impasse? Apparently there may be, provided a distinction is drawn between assemblages from different environments, which can be compared from period to period. This has been attempted by Bambach (*Paleobiology* **3**, 152; 1977), who analysed data from hundreds of fossil assemblages from three different types of environment, as inferred from the facies. The high stress, marginal marine environment always has the lowest faunal diversity and the open marine environment the highest, while the variable nearshore environment has intermediate values. Bambach's data seem to indicate that within-habitat variation in species numbers is small for long intervals of time, and that the number of species has increased by a factor of about four since the mid-Palaeozoic, with variable nearshore environments showing a less pronounced increase than the open marine, while the high stress environments show no significant change. Thus Valentine seems to be partly vindicated, but substantial problems of interpretation remain, notably the factors controlling within-habitat species richness. Bambach speculates that changes through time of availability of food resources might be the most significant, but this is clearly an area demanding much further study.

A. Hallam is Professor of Geology in the University of Birmingham.

aminoglycosides in either whole bacteria or spheroplasts is antagonised in the presence of divalent cations. This could imply that these antibiotics are taken up by a carrier for such ions. Unfortunately no system capable of carrying a wide range of divalent cations has been described. A further significant finding is that calcium ions are less effective in inhibiting streptomycin uptake in a ubiquinone-deficient (*ubiD*) mutant than in the wild type. This indicates that ubiquinone has a direct role in the transport of this antibiotic. There is indeed a very good correlation between susceptibility to aminoglycosides and the possession of respiratory quinones. Thus obligate

anaerobes such as *Clostridium perfringens* which have no respiratory quinones are resistant to aminoglycosides. On the other hand, aerobic organisms possessing ubiquinone or menaquinone are usually sensitive to these drugs. Furthermore, aerobically grown cells of *E. coli* are many times more sensitive to these drugs than are anaerobically grown cells. This suggests that uptake of aminoglycosides is dependent on energy derived from aerobic metabolism.

A simple explanation for the data obtained would be that aminoglycoside transport requires carriers that are dependent on trans-membrane proton motive force. However, in the absence

of an identifiable carrier for such antibiotics Bryan and Van Den Elzen propose an alternative hypothesis. They envisage that EDP-I represents transport of aminoglycosides across the cytoplasmic membrane by a process involving "the aerobic membrane energisation complex". The respiratory quinones probably act directly by binding streptomycin and transporting it across the membrane. A further but less likely possibility is that these quinones act indirectly by activating another component of the complex or a transport protein. EDP-II occurs

because membrane-bound ribosomes have a higher affinity than the transport system for streptomycin. Sensitive ribosomes consequently act as a sink for accumulating drug molecules. This would explain why EDP-II is lacking in strains which are ribosomally resistant to streptomycin. The exact mechanism of aminoglycoside uptake requires verification, but the insights provided by this work should help in the design of aminoglycosides and possibly other antibiotics with increased penetrability. □

## Serum albumin structure and function

from Michael Geisow

ALTHOUGH serum albumin is one of the most familiar and abundant proteins, many aspects of its structure and function remain obscure, although knowledge of more exotic proteins has frequently reached the stage of detailed molecular models. In consequence it is pleasing to be able to report recent developments which give a clearer picture of this much studied, but poorly understood protein.

Roles traditionally assigned to albumin include the transport of fatty acids and other metabolites in plasma, although a host of minor functions continue to be suggested and discussed. Albumin is principally synthesised in the liver and recent work has brought its biosynthesis into line with that of other secretory products of cells. Albumin exists intracellularly with a six amino acid  $\text{NH}_2$ -terminal extension. As in the case of proinsulin, this proform is actually made with a further  $\text{NH}_2$ -terminal 'pre' peptide, which is removed at the sites of synthesis.

The impetus for much new work on albumin stems from the complete sequences of bovine (581 amino acids) and human (582 amino acids) albumins. These are the considerable achievements of J. Brown at Texas University

and B. Meloun of the Czechoslovak Academy of Sciences. The primary structures of other animal albumins are well under way. A striking feature of these sequences is the repeating double-loop motif formed by crosslinks from adjacent cysteine residues (Figure 1). These define three domains or homologous regions of chain (marked I to III in Fig. 1). There are strong amino acid sequence similarities between these domains.

It has become usual to assume that homologous regions of polypeptide form closely similar three-dimensional arrangements. This assumption, together with the considerable folding restrictions imposed by 17 disulphide bridges, has led Brown to construct a plausible model for the albumin domain (11th FEBS Meeting abstracts). His conceptually simple structure consists of six  $\alpha$ -helices (three double loops) which form a roughly cylindrical domain. Albumin is made up of an association of three such cylindrical domains.

The obvious repetition of structural features has led to proposed evolutionary pathways for albumins (Brown *Fedn. Proc.* **35**, 2141; 1976; McLachlan & Walker *J. molec. Biol.* **112**, 543; 1977). Both groups agree that the modern protein descended from duplications of a single double loop struc-

ture. Brown suggests from implied structural evidence that myoglobin and albumin share a common ancestor. McLachlan on the other hand believes that this homology results from convergent evolution of albumin and the globins.

Whatever the ancestry, it seems relevant to ask what function the primitive albumin fulfilled, since the much larger modern protein must represent a sophistication of the original idea. Some answers to this question may have been supplied already by the study of the properties of albumin fragments. For some time workers have known that limited proteolytic treatment of native albumin produces large fragments, evidently by cleavage at unstructured parts of the molecule. The recent sequence information has enabled albumin fragments to be accurately located and released these studies from relative obscurity. Many workers, particularly from T. Peter's group at the Mary Imogene Basset Hospital, New York, have found that individual domains or series of double loops result from mild enzyme treatment. Such fragments are well ordered and may largely retain the conformation they assumed in the intact albumin molecule (Reed *et al. Biochemistry* **14**, 4578; 1975). Even more significantly, fragments retain binding sites associated with the native protein, so it is now possible to allocate these to particular regions of the sequence. On this evidence it seems very likely that the primitive albumin, a double loop, provided a useful binding function in some primordial plasma. Perhaps the evolutionary pressure to extend the number of double loops was strong, not merely to bind other ligands, but also to prevent losses from an equally primitive kidney!

Brown's domain model provides an idealised concept of an albumin-binding site. The cylindrical centre of each domain is a space into which project hydrophobic side chains from the helices. The entrance to this space, formed by the tips of the long disulphide loops in Fig. 1 is lined with positive charges. Lysines and arginines seem to cluster at these points. Such a hydrophobic cavity with localised positive charge is tailor-made for the organic anions which occur so frequently as albumin ligands. It is quite certain that the basic side chains in this site model become labelled when reactive ligands are bound to albumin (Gambhir *et al. J. biol. Chem.* **250**, 6711; 1975). Interestingly, albumin domains seem to have developed some functional specialisations. Fatty acids bind most avidly to domain III while bilirubin and other aromatic ligands prefer domains I and II. Such close structural homology, yet diverse bind-

Fig. 1 The double-loop structure of serum albumin.

Michael Geisow is a member of staff at the National Institute for Medical Research, London.

ing properties, calls to mind the diversification of the immunoglobulin domains.

Albumin recently joined the list of allosteric proteins, with reports that its binding sites were not independent. The binding of a spin-labelled dinitrobenzene is enhanced by 80% when fatty acids are added to albumin and spin label. The spectrum of the bound label also changes, indicating an alteration of its protein environment (Soltys & Hsia *J. biol. Chem.* **252**, 4043; 1976). The affinity of bilirubin for albumin is also increased upon fatty acid binding (Broderson *11th FEBS Meeting*). Arthur Spector reported at the same meeting that fatty acid, presumably bound to domain III, affected spectral properties of an amino acid solely found in domain II. Some caution is still required, since at moderate concentrations most albumin ligands bind at more than one site and it may be difficult to distinguish between cooperative effects and a more simple direct competition. However, Broderson, Torgny and Sjöholm (*J. biol. Chem.* **252**, 5067; 1977) have

shown that albumin does independently bind the antianxiety drug diazepam and bilirubin. These two do not share the same site and the calculated coupling between their sites (expressed as free energy) is less than 50 calorie mol<sup>-1</sup>.

Seen in terms of the domain model of albumin, cooperative phenomena are interesting because they provide a readily available model for studying information transfer between discrete parts of the same polypeptide chain. In a clinical context, these studies are important because they imply that natural ligands and common drugs do not necessarily interact with albumin independently or in a simple competitive sense. Since some drugs are strongly bound by albumin, binding is an important factor in dose levels. The recent results suggest that the free concentration of such drugs could be markedly altered by the dietary fluctuation of plasma fatty acids. It is to be hoped that some of the current speculations and the now huge body of pharmacological measurements connected with albumin can soon be integrated. □

products are continually required for differentiation away from mesothorax.) These mutants produce transformations in the entire compartment normally requiring the gene product.

P. A. Lawrence (MRC Laboratory of Molecular Biology, Cambridge) described evidence that some segments are further subdivided into anterior and posterior compartments; here the engrailed gene product is apparently required exclusively for the posterior cells. The gene product is essential for the proper development of the posterior compartments and for the precise delineation of the boundary between anterior and posterior cells. He described unpublished work of G. Struhl (MRC, Cambridge) on the proboscis which showed that it is divided into anterior and posterior compartments and also dependent on the engrailed gene in a homologous way to the thoracic segments.

Another mutant which can be viewed within the same conceptual framework is the mutant *transformer* in which XX genetic females are made into almost perfect males.

R. Nöthiger (University of Zurich) described experiments which demonstrated that all embryos contain two separate primordia, one for male and one for female genitalia, each sex containing one 'silent' primordium. By making large *transformer* clones in an otherwise wildtype female, Nöthiger was able to conjure up a complete male set of genitalia in an intact female; *transformer* clones in the female primordium produced loss of part of the female genitalia.

The picture emerging from these four talks is one of a series of 'master' genes, which are activated in particular places, and which control the development of precisely defined pieces of the insect.

At the cellular level, O. Siddiqui (Tata Institute, Bombay) has studied the development of the *Drosophila* nervous system in a range of chemosensory mutants some of which show temperature sensitive development of the sensory pathway. The development of the nervous system was also the subject of a talk by J. White (MRC, Cambridge) who has used mutants and laser microsurgery to investigate the pattern of cell lineage in the ventral nerve cord of nematodes. Removal of individual cells by laser revealed that inductive interactions can occur, and that the vulva precursor cells can regulate their proliferation to compensate for the experimental elimination of specific cells. One alternative to conventional genetic approaches to the study of development is the use of cell-free systems, two of which were described at the meeting. R. Laskey

## Genes in development

from Ron Laskey, Peter Lawrence and Eddy De Robertis

A conference on Developmental Genetics was convened by the Accademia Nazionale dei Lincei and held in Rome on October 31–November 1, 1977.

PARTICIPANTS in two days of talks held at the Accademia Lincei in Rome—the oldest scientific foundation in the modern world, tried to tackle the ancient problem of how eggs plus genes produce animals. It was symptomatic of the renewed interest in *Drosophila* that the whole of the first day was devoted to that fly. E. B. Lewis (Cal-Tech) revealed some exciting new results in the bithorax system, the complex genetic locus responsible in part for the segmented pattern of the larva and adult fly. The scanning electron microscope showed up some hitherto unremarked distinctions between the different segments in the newly hatched larva so that the segmental patterns of new mutations and deficiencies could be studied. Flies deficient for the whole of the bithorax

complex developed only as far as the first stage larva, which consisted entirely of mesothoracic segments. Further analysis of partial deficiencies and 'constitutive' mutants indicated a group of new genetic functions (to the right of *pbx*) which Lewis called *polythoracic* and which are apparently necessary for the normal differentiation of the abdominal segments—all regarded as structures which diverge from the archetypal mesothorax.

A. Garcia-Bellido (Madrid University) pursued the problem of how the genes of the bithorax system are switched on in particular places. In his view the bithorax system responds to positional information in the egg; a process which can be interfered with in at least three ways: (1) the positional information can be disturbed, for instance by ether treatment of the blastoderm-stage egg. This results in groups of cells developing faithfully into a portion of inappropriate segment; (2) the same phenotype can be produced by certain mutations (*Rgpbx*, *Rgbx*) in genes which might produce regulatory molecules involved in the response of the bithorax system to the positional information; (3) mutations in the bithorax system itself (whose

The authors are at the MRC Laboratory of Molecular Biology, Cambridge.

(MRC, Cambridge) described a *Xenopus* egg system in which chromatin assembly takes place. Each egg can convert an amount of DNA equivalent to 6000 nuclei into regularly spaced nucleosomes in the absence of DNA synthesis. Laskey has found that all the materials required for nucleosome assembly cofractionate in a single particulate fraction, suggesting that histones are organised into a nucleosome precursor complex before they bind DNA.

G. Tocchini-Valentini (CNR, Rome) described a *Xenopus* oocyte system which elongates and terminates replicating chromatin. But neither he nor Laskey could find evidence for initiation of DNA replication *in vitro*, although it can apparently be seen in micro-injected eggs.

The fusion of genetic and molecular approaches to the study of development provided a stimulating two-day meeting. □

## Problems with pollen

from Peter D. Moore

PALYNOLOGISTS studying sediments of Quaternary origin have certain advantages over colleagues concerned with older materials for there is a higher likelihood that both the taxa and the plant communities with which they deal remain extant. There are exceptions, of course, such as the tundra communities which occupied low latitudes and low altitudes in the periglacial conditions obtaining at the close of the last glaciation. One cannot assume that tundra communities of modern high latitudes or high altitudes have the same composition. But generally the Quaternary palaeoecologist uses the present as a Rosetta stone by which to interpret the past.

Reconstruction of the past mosaic of plant communities on the basis of a subfossil assemblage of pollen grains is currently being greatly assisted by accumulating information concerning modern pollen rain from contemporary plant communities. It is remarkable that for many decades palynologists have been content to interpret their fossil data without such information. Fortunately, however, indications from most modern pollen rain studies have confirmed the broad correlation between vegetation and its pollen output which has always been assumed. The work of Lichti-Federovich and Ritchie (*Rev. Palaeobotan. Palynol.* 7, 297;

1968), for example, on surface lake sediments in central Canada, showed that the major forest belts of the region could be distinguished on the basis of their pollen spectra. Certain anomalies were evident, such as the transport of spruce pollen into the treeless tundra areas of the north, but there was generally an acceptable agreement between vegetation and pollen rain.

Such studies have been chiefly concerned with the major components of both vegetation and the accumulating pollen assemblage, but detailed interpretation of palaeodata may also depend on the presence of relatively small quantities of a taxon with narrow ecological or phytosociological limits. It is often possible to infer the presence of certain vegetation types and hence certain habitats and microenvironments on the basis of the occurrence of these 'indicator types.' In this respect the work of Janssen has been of great value (for example *Ecol Monogr.* 37, 145; 1967). He has used the technique of comparing vegetation transects along environmental gradients with the pollen accumulating along them; in this way it is possible to observe how closely certain pollen types are associated with particular plant communities, even when their overall representation in the pollen spectrum is small.

On the basis of Janssen's work it is evident that pollen samples taken from the surface sediments of a water body will differ quite considerably from those in adjacent reed swamps or woodlands. So when interpreting fossil data, the nature of the sediment under consideration should be taken into account. One further aspect of this type of study which still lacks detailed documentation is the degree to which surface samples of the same type and under the same vegetation vary in their pollen composition. Is it possible that the variation within certain plant communities is greater than that between communities? In many surface pollen studies it has not been possible to glean this type of information because duplicated samples have been bulked before analysis, but a recent study of pollen rain in Alaska by Birks (*Can. J. Bot.* 55, 2367; 1977) now provides the necessary information for certain vegetation types.

Birks distinguished four major vegetation types, *Picea glauca* forest, which contained *Betula glandulosa* as a shrub layer, *Betula glandulosa* dominated shrub-tundra, *Populus balsamifera* stands within the forest, and open tundra vegetation dominated by *Dryas integrifolia*. In addition to the detailed description of these vegetation types, Birks collected samples of moss polsters, surface muds from lakes and superficial peat samples from sedge swamps from each of the plant com-

munities. A visual inspection of the data resulting from the analysis of these samples suggests that certain pollen characteristics are specifically associated with certain vegetation types. For example, only in samples originating from the *Populus*-dominated stands does the *Populus* pollen type occur at levels greater than about 2%, and only in the *Dryas* tundra does the level of *Dryas*-type pollen exceed about 2%.

Birks has subjected the pollen data to principal coordinates analysis, in which the pollen samples are ordinated with respect to one another on axes which represent dissimilarity. On one axis he shows a polarisation of the *Populus* forests and the *Dryas* tundra with the *Picea* forests and shrub-tundra forming an undistinguishable group in the centre. On the other axis the extremes are occupied by swamp peat samples and moss polsters respectively. One of the most important criteria which may account for this latter separation is the relative proportion of Cyperaceae pollen in the samples. One must conclude from this analysis that the degree of variation found within both the *Picea* forest and the shrub-tundra samples are such that the two vegetation types cannot be separated on the basis of their pollen spectra. This being so, one would not be able to differentiate between them in subfossil pollen assemblages.

This analysis was based only on those pollen types having a relative abundance of 5% or more of the total pollen sum in at least one of the samples; in other words, only the major pollen types are used for differentiation. There remains the possibility that indicator types of lower abundance could be used. Inspection of the pollen data suggests that this is unlikely to be a particularly helpful approach. Only one terrestrial herb taxon, *Astragalus*, is found in a single *Picea* forest sample but in none of the shrub tundra samples. On the other hand there are ten such taxa found scattered among the shrub-tundra samples which are not found in the spruce forest sites. As a final straw at which to clutch, one could compare the overall herb pollen diversity in the two sets of samples. Inspection indicates that the shrub-tundra has a generally larger component of low abundance, herbaceous taxa, possibly reflecting the open vegetation. A comparison of the two sets of data using a diversity index such as the Shannon-Wiener function might provide a means of resolving these two communities on the basis of their pollen spectra. Meanwhile, the fact that such problems can arise in the separation of modern vegetation types should encourage caution among those who seek to interpret fossil assemblages. □

## Applications of proportional chambers and drift chambers in high-energy physics and other fields

G. Charpak\*

*Proportional counters, which were superseded in high-energy physics by developments such as spark and bubble chambers, have recently undergone modifications which have considerably increased their space and time resolution. These modified counters are finding applications not only in high-energy and nuclear physics but also in biology and medicine.*

PROPORTIONAL counters were an essential tool in nuclear physics until the beginning of the 1950s. Because of their practical importance their properties were extensively investigated and to a large extent well understood<sup>1</sup>. The powerful properties of structures different from the simple cylindrical shape were overlooked, however, and as we shall see, the multiwire structures permit space and time resolutions that are orders of magnitude better than those of cylindrical structures.

The counters were used for many purposes: counting of ionising radiations, measurement of their energy, localisation with an accuracy, both in space and time, usually set by the counter size. They have played only a minor part in the development of nuclear or sub-nuclear physics in the last quarter of a century, when they were superseded by the scintillation counters, faster and more versatile, the nuclear emulsions, the spark chambers of various types localising the position with accuracies better than a millimetre; the bubble chambers, visualising spatial configurations in particle reactions of an incredible complexity, and many other detectors.

A recent development<sup>2</sup>, based essentially on the same principles as the cylindrical counter but making a proper use of multiwire structures, is, however, making a radical change in the experimental strategies in low-energy and high-energy physics, and has also begun to find applications in several other fields, such as crystallography and medicine.

### Ordinary cylindrical proportional counters

Since this basic instrument is described in many text books, let us mention only its most salient features. It is typically made of a cylindrical cathode with a thin wire anode at its axis. The gas filling usually consists of a noble gas mixed with organic molecules. In such a structure the electrical field decreases as the inverse of the distance  $r$  to the axis. In the region close to the wire, the field is so intense that free electrons acquire enough energy in a mean-free path to ionise the molecules of the gas, thus leading to an avalanche of electrons localised close to the surface of the wire. A typical collision mean-free path at atmospheric pressure is  $1\ \mu\text{m}$ . The maximum size of an avalanche is around  $10^6$  electrons. For gains exceeding this limit, dependent on the gas and geometry, the ultraviolet photons emitted by the excited atoms induce a propagation of the discharge. The radial extension of an avalanche at atmospheric pressure is thus close to  $20\ \mu\text{m}$  only.

Since the process of amplification leading to the detectable pulse is produced after the ionisation electrons have reached the region close to the anode, the time of appearance of the pulse will depend on the initial position of the electrons, and will vary with the position of

the particle. This introduces an uncontrolled jitter in the timing of the particles, which reaches a few hundred ns for 1 cm diameter. This is one of the reasons why these counters were superseded by the scintillation counters, which, although more expensive, have a 100 times better resolution.

**Fig. 1** A multiwire proportional chamber: *a*, schematic view showing the cathode planes closely spaced around anode wires; *b*, electric field equipotentials and field lines in a multiwire proportional chamber. The effect on the field of a small displacement of one wire is also shown.

\*CERN, Geneva, Switzerland

**Fig. 2** Time development of an avalanche in a proportional counter. A single primary electron proceeds towards the anode (a), in regions of increasingly high fields, experiencing ionising collisions (b); owing to the lateral diffusion and photoionisation, a drop-like avalanche (c), surrounding the wire, develops. Electrons are collected in a very short time (1 ns or so) (d), and a cloud of positive ions is left, slowly migrating towards the cathode (e). Whether the cloud surrounds the wire or not, depends on the nature of the gas.

We shall see that by giving up the cylindrical structure, two steps have been accomplished: both the time and position of the particles can be measured with a high accuracy.

### Multiwire proportional chambers (MWPC)

The electrical structure of the chamber comprises thin, parallel, and equally spaced positively charged wires, sandwiched between two cathode planes. Figure 1 shows the electric field potentials in such a structure. We see that in the region close to the wire the electrical field is exactly the same as in a cylindrical structure. In other words, as soon as an electron liberated in the gas by an ionising radiation has reached the region of multiplication, it proceeds exactly as in a cylindrical counter. Although the wires are independent for the multiplication process, one may wonder whether their capacitive coupling does not short-circuit them and thus reduce them to a single electrode when they are as close as 1 mm. Indeed, when an external fast pulse is fed to one wire we observe the propagation of the pulse with the same sign, from wire to wire. This is not the case, however, with a pulse generated by the amplification process, and here we have to look into the detail of the pulse mechanism to

understand some of the properties which are responsible for the success of this type of structure.

Figure 2 shows the time development of the avalanche started by a single electron around a wire. Within a time shorter than a nanosecond, the avalanche results in a thin cloud of positive ions close to the wire, usually in a non uniform way. It was at first believed that the avalanches surround the wire. More recent experiments show that this is not usually the case and that this hypothesis is not required to explain the positive pulses on all electrodes neighbouring a sensing wire.

It is important to realise that the collection of the electrons does not usually give rise to a detectable pulse: it is too fast and too small. Its size is proportional to the potential drop experienced by the electrons while travelling in the gas, which is negligible since they travelled only a few  $\mu\text{m}$ . It is the motion of the positive ions that is responsible for pulses with the following characteristics. (1) Pulses are negative in the wires but positive in all surrounding electrodes. This is one essential feature: the neighbouring wires detect a positive pulse. Thus, the active wire is easily distinguished from its neighbours. It suffices to use amplifiers that are sensitive to one sign. (2) The pulses are fast-rising. The field is so intense close to the wire, usually above  $10^5 \text{ V cm}^{-1}$ , that rise-times of the order of 10 ns are observed at the beginning of the pulse, which then slows down and lasts for  $\mu\text{s}$ .

The important properties of a MWPC are as follows. (1) The space resolution is apparently dependent on the wire spacing since every wire behaves as an independent counter. In practice, 1 mm wire spacing is common for small structures (20 cm), 2 mm for large structures (200 cm), and chambers of  $5 \times 5 \text{ m}^2$  are being operated with 3 mm wire distance. (2) The space resolution of a chamber can be much better than the wire spacing. The coordinate of the avalanches along the wire can be measured by different methods. Accuracies better than  $100 \mu\text{m}$  can be obtained. Since a two-dimensional read-out is essential for the detection of neutral radiations, I shall discuss the recent progress in such measuring methods in connection with some applications. (3) The time resolution is also dependent on the wire distance. The closer the wire spacing the shorter is the time taken by the electrons liberated in the gas by an ionising particle to find a nearby wire to be detected. Practically 30 ns resolution is obtained with 2 mm wire spacing. (4) The maximum counting rate is limited locally by the space charge created by the positive ions. The chambers show a loss of gain at rates of the order of  $10^4 \text{ events s}^{-1} \text{ mm}^{-2}$ . Rates of several million counts  $\text{s}^{-1}$  are common in the practical use of the chambers.

### Drift chambers

The time lag between the appearance of a pulse and the distance to the wire of the ionising track can be used to measure this distance<sup>2,3</sup>. Typically it takes 200 ns for an electron to drift 1 cm in the chamber. This has given rise to an important class of detectors: the drift chambers. Measuring the time is very simple. Chambers with very large wire spacings can be used to make economical, large-size detectors. Figure 3 shows the structure of such a chamber. One example is given by the chambers built at Daresbury for an experiment at CERN: size 3.5 m, wire distance 12 cm, accuracy better than  $350 \mu\text{m}$  throughout the active area<sup>4</sup>. The intrinsic

**Fig. 3** Principle of construction of the adjustable field multiwire drift chambers: a, schematic view; b, equipotential lines. Cathode wires are connected to uniformly decreasing potentials, starting from ground in front of the anode. Field wires reinforce the field in the transition region to the next cell.

**Fig. 4** Computer display of a high-energy interaction viewed by a system of multiwire chambers. At an intersection of the CERN proton storage rings, a system of 70,000 wires in a magnetic field detects the coordinates of the particles from one interaction. Typical rates: 150,000 interactions s. Background:  $10^6 \text{ s}^{-1}$  chamber, resolution time  $\sim 100 \text{ ns}$ .

accuracy is of the order of  $50 \mu\text{m}$ , as shown in smaller chambers used in experiments<sup>3</sup>.

### Applications of MWPC and drift chambers

MWPC and drift chambers are now routine instruments in high-energy physics. They have in most cases replaced the spark chambers and sometimes the scintillation hodoscopes. They permit the detection of very rare events, for instance, in the hunting of new particles immersed in an enormous background of common reactions. The high time resolution and space resolution are the essential properties for this research.

Very large systems are in operation. Typical in this respect is the large detector equipping one intersect of the CERN storage rings. Set in a gap of about 10 m length, 1 m height, and 2 m width, chambers with wires of 1 m or 2 m length detect the trajectories of the particles produced in the head-on collisions of two 30 GeV protons. Figure 4 shows a complex event reconstructed by a computer from the data collected by 70,000 wires, 2 mm apart.

Many bubble chamber systems now use external systems of MWPC to give supplementary data on the particles emerging from the chambers.

Chambers are also now commonly used as detectors in nuclear physics in the focal plane of magnetic spectrometers, where

**Fig. 5** Accuracy along the wire. Histograms of the coordinates of the charge centroid along a wire for three positions of a collimated beam with  $200 \mu\text{m}$  separation (ref. 6).

accuracies of a fraction of a millimetre over lengths of the order of 1 m are easy to attain. Typical in this respect is the detector developed at the Massachusetts Institute of Technology<sup>5</sup>, where an accuracy of  $130 \mu\text{m}$  ( $2\sigma$ ) and an angular resolution of  $17 \text{ mrad}$  ( $2\sigma$ ) is obtained for relativistic electrons in the focal plane of a spectrometer.

Outside physics, MWPC are now being applied to problems of localisation of X rays and neutrons in medicine. These radiations produce in the gas low-range ionising secondaries which do not emerge from the chambers. It is essential to localise the coordinates of the avalanches from a single gap. Since the very beginning of the MWPC, the groups working in the field of neutral radiations have designed various analogue methods to measure the coordinates of avalanches along the wires<sup>2,6</sup>. They are based on the propagation of the signals in delay lines or resistive electrodes. A more recent development<sup>7</sup> illustrates the considerable accuracy that can be reached both along the wire and in the interpolation between wires. It is based on the measurement of the centroid of the pulses induced on cathode strips. Figure 5 shows the positions of three 1.5 keV X-ray beams, spaced about  $200 \mu\text{m}$  apart along the wire. A resolution of  $\sigma = 35 \mu\text{m}$  is obtained, of which only  $7 \mu\text{m}$  is contributed by the measurement, the remainder corresponding to the physical size of the charge distribution. The surprising thing is that this method gives also the position of punctual charge distributions, characteristic of X-ray secondaries, between the wires. It was for a long time postulated that the accuracy of a chamber is limited by the wire spacing. This is wrong in two cases: if the charges are distributed among several wires, the centroid method will give the interpolation; and if the charges are punctual, the centroid method will give the azimuth of the avalanche on the wire with an accuracy of about  $5^\circ$  for 2 mm wire spacings. This is illustrated by the radiograph of the word CERN<sup>7</sup>, cut out in a copper mask with letters of  $50 \mu\text{m}$  width, 1.5 mm height. Although the wire distance is 2 mm, a continuous response is obtained with all the avalanches occurring on the wire centred on the letters only (Fig. 6).

**Fig. 6** Radiograph of the word CERN. Dimensions of the word: 1.5 mm  $\times$  4 mm. Avalanches on only one wire: 2 mm wire spacing<sup>7</sup>.

This method will certainly be widely used in all problems where the two-dimensional read-out is important.

The most promising application of the chambers so far seems to be in the detection of X rays<sup>8,9</sup> or neutrons<sup>10,11</sup> diffracted by crystals made of large molecules, or by organic tissues with a regular structure<sup>12</sup>.

At CERN, a spherical drift chamber has been developed<sup>13</sup> to be used with the synchrotron radiation with the Orsay electron storage rings. Its present characteristics are: an angular aperture of  $90^\circ$ , an angular accuracy of  $2.5 \text{ mrad}$ , an efficiency of 100% for 8 keV photons, and a possible ultimate rate of  $10^6 \text{ s}^{-1}$ . A gain of at least 1,000 in the speed of data-taking is expected with respect to the conventional detection methods used with diffractometers. This opens up new fields of research, for instance in the study of quickly evolving structures.

Nuclear medicine also has problems of imaging, chiefly in the detection of X rays that are much more energetic. The minimum is the radiation of 27 keV emitted by  $^{125}\text{I}$ , commonly used in labelling the thyroid tissues. The main interest, however, lies in radiations well above 100 keV, where the chambers are quite inferior to the widely used scintillation cameras in two respects: the low efficiency, and the poor spatial resolution due to the large range of the

secondary electrons in the gas. So far this has limited the applications to fields where radiations below 100 keV are of interest. Typical in this respect is the work undertaken at Rutherford Laboratory<sup>14</sup>, where a chamber measures bone densities with the 42 keV X rays emitted by <sup>253</sup>Gd. The localisation of the X rays can be better than with NaI cameras<sup>15</sup> and they cost far less.

A possible way of overcoming the low density of the gas is to use a drift space filled with suitable converters. Several groups<sup>16,17</sup> are at present actively developing this approach. Efficiencies of up to 15% with accuracies of a few millimetres can be reached at 500 keV.

These chambers suffer from two drawbacks: no energy resolution, and a poor resolution time close to 0.5  $\mu$ s. They find a possible important application for positron cameras. The correlation of the two annihilation  $\gamma$ -rays give such a good selection of non-scattered  $\gamma$ -rays that it compensates partially for the lack of energy resolution. The poor time resolution may be a fatal obstacle to the use of this technique for medical applications. Present positron cameras based on NaI counters can operate with 10-ns resolution times. They lead to such expensive instruments, however, and the technique of positron imaging could be so powerful with good, cheaper detectors, that it is still worth making a thorough investigation of the possibilities offered by MWPC, which are better suited to large size, low cost detector systems than are the NaI cameras.

## Conclusions

Multiwire chambers and drift chambers offer an interesting example of a technology developed in high-energy physics laboratories with a fair chance to find important applications in fields remote from high-energy physics. Whenever methods require the measurement of the position of ionising radiation, a possible application of these detectors can be found; this offers a good opportunity to make use of the huge effort in capital and skills invested by experimental groups working in high-energy physics.

## Past volcanism revealed by Greenland Ice Sheet impurities

C. U. Hammer

Geophysical Isotope Laboratory, University of Copenhagen, Haraldsgade 6, DK-2200 Copenhagen, Denmark

*Past volcanic aerosols have left Greenland Ice Sheet layers with elevated specific electrical conductivities that can often be used to estimate the magnitude of individual eruptions. Records of past volcanism may, therefore, be extended and help solve the problem of possible climatic correlation.*

PRECIPITATION falling on the two large ice sheets in Antarctica and Greenland is extremely pure<sup>1,2</sup>. The low background impurity level makes polar glacier ice suitable for investigating past violent volcanism in the form of additional impurities deposited shortly after the eruptions and stored in the ice.

Disregarding gases and organic material<sup>3</sup>, the deposition of impurities on the Greenland Ice Sheet is of the order of 50 kg km<sup>-2</sup> yr<sup>-1</sup> in times of low volcanic activity<sup>4</sup>. Assuming that the mean aerosol residence time in the upper troposphere is approximately 1 month<sup>5</sup>, the above figure corresponds to a background aerosol load of the order of 10<sup>9</sup> kg in the upper northern hemisphere troposphere, which is close to an estimate based on Mauna Loa data<sup>6</sup>. Aerosols of volcanic origin may be detectable as increased aerosol fall-out, if their contribution to the upper tropospheric aerosol load is significant relative to the above mentioned background.

Violent volcanic eruptions inject into the atmosphere large quantities of impurities, part of which significantly reduces the

atmospheric transmissivity on a global or hemispheric scale up to three years after the eruptions. For example, the Krakatau (1883) and the Katmai (1912) eruptions caused a 20% reduction of the Northern Hemisphere atmospheric transmissivity by each injecting 16  $\times$  10<sup>9</sup> kg aerosol material into the northern stratosphere<sup>6</sup> (Krakatau probably injected a similar amount into the southern stratosphere as well). Assuming that this material is deposited within 1 or 2 yr, the average volcanic contribution to the total upper northern tropospheric aerosol load in these periods was probably of the same order as the non-volcanic background (10<sup>9</sup> kg).

Therefore, in spite of the spreading of the eruption cloud and the complicated deposition pattern caused by non-uniform wash-out by precipitation, any 'clean-air' location must be expected to receive significantly elevated amounts of aerosol fall-out in periods of high volcanic activity, at least in the same hemisphere. The most favourable areas for tracing past volcanism are the high altitude regions of the two large ice sheets, where the background concentration of non-volcanic aerosols is low. The Greenland Ice Sheet has the additional advantage of being fed by relatively frequent, heavy snow falls. The impurity concentration in the snow is proportional to the temporary aerosol load in the air<sup>7</sup> and since the snow is accumulated with little melting and no run-off, analyses of absolute-dated Greenland cores provide a record of atmospheric turbidity, essentially above ~ 2,000 m altitude.

None of the impurity nor its constituents has so far been shown

to be a specific volcanic tracer. Previous analyses<sup>8</sup> performed on an ice core from Dye 3 (Fig. 1), indicated that most solid micro-particles above  $0.4\text{ }\mu\text{m}$  radius are continental surface dust, even during periods of high volcanic activity. But the high sulphate content in the stratosphere shortly after recent violent eruptions suggests that most of the volcanic material in the stratosphere consists of sulphate, originating from the release of  $\text{H}_2\text{S}$  and  $\text{SO}_2$  (ref. 9). Hence, elevated concentrations of  $\text{H}_2\text{SO}_4$  and/or  $(\text{NH}_4)_2\text{SO}_4$  might be detectable in Greenland snow up to three years after the volcanic event. Impurities, particularly of sulphuric acid, greatly influence the specific electrical conductivity,  $\sigma$ , of the melted ice, and as we analysed thousands of samples, this simple parameter was chosen as an indicator of volcanic activity. Of course,  $\sigma$  profiles cannot replace the comprehensive chemical analysis program that has commenced<sup>10</sup>, but they do reveal important characteristics of volcanic fall-out and may be used as a simple means of showing which of the numerous core increments are promising objects for detailed geochemical analyses.

### Volcanic impurity concentration index

Using  $\sigma$  as a volcanic activity indicator implies a comparison of  $\sigma$ -profiles along absolute-dated ice cores with historical records of the volcanic dust production. But such records based on objective measurements only span the past 100 years. Extending the comparison beyond this period, therefore, necessitates using records based on indirect evidence, such as the total amount of material ejected. In assessing the relative magnitude of the eruptions as dust producers, Lamb<sup>11</sup> includes historical accounts of (non-instrumental) observations of optical phenomena in the upper atmosphere. Lamb's volcanic dust production index (v.d.p.i.) is shown in Fig. 2a dating back to 1770. There is only one adjustment: the v.d.p.i. for the Shtyubelya Sopka eruption at  $52^\circ\text{N}$  in 1907 (equal to that of Katmai, 1912) has been reduced by a factor of 5 in view of radiation measurements in the  $30\text{--}60^\circ$  northern latitude belt<sup>12</sup>. The open bars are mainly derived from an assumed relationship between climatic temperature anomalies and atmospheric dust veils.

In order to estimate the volcanic ion concentration in Greenland precipitation, the v.d.p.i. has to be corrected to account for the residence time of the aerosols in the atmosphere and the non-uniform distribution pattern of the fall-out. The correction has been made by accounting for (1) a temporal distribution of the fall-out corresponding to a residence time of 1 yr for aerosols in the high latitude stratosphere (2) a time lag of 1 yr for the high northern latitude fall-out of volcanic debris originating from eruptions south of  $50^\circ\text{N}$ , and (3) spreading of the eruption cloud on its travel to high northern latitudes by using a correction factor  $F$  on the v.d.p.i. of all eruptions. For simplicity, and with a view to fall-out data for fission products<sup>13,14</sup>, supplemented by total  $\beta$ -activity data from the polar ice sheets<sup>15,16</sup>, the  $F$ -factor is equal to 1 for latitudes of eruptions north of  $50^\circ\text{N}$ , 0.5 in the  $20^\circ\text{--}50^\circ\text{N}$  latitude belt, 0.2 in the  $20^\circ\text{S}$  to  $20^\circ\text{N}$  belt and 0.07 for eruptions south of  $20^\circ\text{S}$ .

As precipitation contains a representative sample of the aerosols in the precipitating air mass, the procedure described above leads to a new index (Fig. 2b), which may be called a volcanic impurity concentration index (v.i.c.i.) for high northern latitude precipitation.

### Material and techniques

Specific conductivity profiles have been measured along three ice cores recovered from North (Hans Tavsén), Mid (Crête) and South (Dye 3) Greenland (Fig. 1), all recovered under the Greenland Ice Sheet Program. The Crête  $\sigma$  profile is continuous through the period AD 1770–1972. The Crête and Dye 3 cores are absolute-dated<sup>16</sup>, whereas the Hans Tavsén core is dated by ice flow model considerations back to 1815 and from then on by counting annual cycles in the micro-particle concentration<sup>16</sup>.

The cores were sampled in sequence averaging four samples for each annual layer as revealed by seasonal cycles in heavy oxygen-isotope concentration<sup>16</sup>. The individual samples were cut from the cores at  $-12^\circ\text{C}$  in a clean air bench after removal of a more

Fig. 1 The Greenland Ice Sheet with the drill sites, where the investigated ice cores were recovered: Dye 3 (elevation  $e = 2,480\text{ m}$ ; snow accumulation rate  $a = 49\text{ g cm}^{-2}\text{ yr}^{-1}$ ); Crête ( $e = 3,170\text{ m}$ ;  $a = 25\text{ g cm}^{-2}\text{ yr}^{-1}$ ); and Hans Tavsén ( $e = 1,200\text{ m}$ ;  $a = 17\text{ g cm}^{-2}\text{ yr}^{-1}$ ).

than 5 mm surface layer that contains essentially all of the relevant contaminants in an undamaged core. Occasional cracks and other regions of possible deep contamination were avoided. The ice samples were melted in clean plastic beakers, and the solid micro-particle concentration including particles down to  $0.05\text{ }\mu\text{m}$  radius, was measured by a light scattering method<sup>8</sup> and also in many cases by the standard Coulter counting method. Often the pH was measured by standard procedures. The conductivity measurements required larger amounts of water. In order to save core material, it was necessary to dilute most of the samples up to three times with deionised, redistilled water ( $\text{pH} = 5.6$ , specific conductivity  $\sigma = 130\text{ }\mu\text{S m}^{-1}$ ). This introduced some false noise in the low  $\sigma$  values, and perhaps up to a 15% increase in the  $\sigma$  background. The mixtures were allowed to saturate with the carbon dioxide in the ambient air at  $25^\circ\text{C}$ , which changed  $\sigma$  by less than 10%, because both the ice<sup>17</sup> and the dilute were near saturation beforehand. Finally,  $\sigma$  was determined by standard procedure.

### Results and discussion

The annual mean solid micro-particle mass concentration at Crête, determined by total number and size distribution analyses, is plotted in  $\mu\text{g per kg}$  of ice in Fig. 2d. There is no significant correlation with the v.i.c.i. in section b, which indicates that

Fig. 2 Volcanic activity compared with impurity profiles along an ice core from Crête, Greenland, spanning the period 1770-1972. *a*, Lamb's volcanic dust production index (v.d.p.i.); open bars refer to estimates mainly based on an assumed relationship between climatic temperature anomalies and atmospheric dust veils. *b*, Volcanic impurity concentration index (v.i.c.i.) for high northern latitude precipitation, derived from the v.d.p.i. by correction for latitudinal spreading of the eruption cloud and for residence time of aerosols in the atmosphere. The Icelandic Laki eruption, 1783, stands out with a v.i.c.i. more than twice the second highest v.i.c.i. (1795). *c*, Specific conductivity of melted samples of annual precipitation. Values exceeding the mean in the volcanically quiet period 1920-60 are set out in black. Significant correlation with the v.i.c.i. shows that part of the soluble impurities of volcanic origin. The value for 1783 is more than twice the second highest. *d*, Insoluble micro-particle mass concentration (in  $\mu\text{g per kg of ice}$ ). The bulk of insoluble impurities must be continental surface dust, because the curve has no correlation to the v.i.c.i., and no increasing trend in the industrial period.

essentially all of this fallout at Crête is of continental surface origin. Furthermore, the lack of significant increase in the upper part of curve *d* shows that little, if any, industrial solid dust reaches Central Greenland.

According to Fig. 2b the Icelandic Laki eruption in 1783 (historically the greatest lava extrusion, some  $12 \text{ km}^3$ , on Earth) was presumably responsible for the highest fall-out of volcanic debris in Greenland in the past 200 years, which suggests the 1783 ice layer as favourable for a pilot test. Figure 3 shows  $\sigma$  profiles through the annual layers deposited in the period 1780-86. The shaded part of the  $\sigma$ s represents the contribution of  $\text{H}^+$ ,  $\sigma_{\text{H}^+}$ , calculated from the pH data and corrected for  $\text{CO}_2$  induced ions. The Laki eruption is revealed in the Dye-3 and Crête cores by elevated  $\sigma$  and  $\sigma_{\text{H}^+}$  values in the layer previously absolute-dated at 1783. In the Hans Tavsén core the peak values appear in a layer dated at 1784 mainly by the less accurate ice flow model calculations. The Hans Tavsén peaks are bipartite due to a layer of refrozen meltwater that has percolated from a younger summer layer. At this station, located on a medium altitude, separate ice sheet, and only some 15 km from snow-free areas, the ice chemistry is complicated by the dust content being more than an

order of magnitude higher than at the other stations. The  $\sigma_{\text{H}^+}$  shows that melted Hans Tavsén precipitation has a strong acid reaction only in periods of heavy volcanic fall-out.

In Fig. 2c the annual mean  $\sigma$  values at Crête are plotted over the period 1770-1972. Those exceeding the 40 yr mean  $\sigma$  value ( $170 \mu\text{S m}^{-1}$ ) for the volcanically quiet period 1920-60 are set out in black. The variability of  $\sigma$  in this period should be considered as noise, and deviations of the same order in the rest of the curve are therefore insignificant. Nevertheless, the small rise in  $\sigma$  in the late 1910s may be significant, because the HCl and HF production in 'the valley of 10,000 smokes' created by the Katmai eruption has been estimated<sup>18</sup> at  $1.4 \times 10^9 \text{ kg yr}^{-1}$  up to 1920.

Sudden rises in v.i.c.i. and  $\sigma$  generally occur simultaneously or with a short time lag in  $\sigma$ . As for eruptions south of  $50^\circ\text{N}$  any time lag in  $\sigma$  between -1 and +1 year may occur, in view of the general 1 yr shift introduced when transferring the Lamb's v.d.p.i. into the v.i.c.i. in Fig. 2b. Eruptions north of  $50^\circ\text{N}$  should be revealed by sudden increases in  $\sigma$  with time lags between zero and +1 yr, assuming the ice core time scale to be exact.

Although Lamb's v.d.p.i. (Fig. 2a) is not specifically designed to represent the volcanic production of gases and ionic com-

**Table 1** Background composition of impurities in melted Greenland glacier ice

pounds, a statistical analysis of the v.i.c.i. and  $\sigma$  time series shows a highly significant correlation coefficient ( $R = 0.6$ ;  $P > 99.9\%$  for  $n = 20$  degrees of freedom). Furthermore, Fourier spectral analysis shows less than 1 yr time lag for any frequency higher than  $0.02 \text{ yr}^{-1}$ , the coherence being of the order of 0.6 for the same frequencies.

If, consequently, elevated  $\sigma$  values are accepted as indicative of fallout of volcanic acids produced in the northern hemisphere, Fig. 2c suggests that unnoticed eruptions of considerable magnitude took place around 1810. Furthermore, the v.d.p.i. for the Askja eruption, 1875 (and Pavlof, Alaska, 1786?) may have been overestimated, as an Icelandic eruption of the estimated magnitude would probably be revealed by more than a barely significant increase in  $\sigma$ .

Some of the available ice sheet chemistry data are presented in Table 1. They suggest a simple explanation of the  $170 \mu\text{S m}^{-1}$   $\sigma$  background at Crête being due mainly to the  $\text{H}^+$ ,  $\text{Na}^+$ ,  $\text{NH}_4^+$ ,  $\text{SO}_4^{2-}$ ,  $\text{Cl}^-$  and  $\text{HCO}_3^-$ . First, quite a few elements (such as, Si, Al and Mg) may be disregarded, because they are mainly present in solid micro-particles that do not contribute to  $\sigma$ . For example, using the Al content ( $5 \mu\text{g per kg ice}$ ) as an indicator of igneous rock material<sup>21</sup> gives an order of  $60 \mu\text{g}$  of insoluble material per kg of ice, in agreement with the overall mean value in Fig. 2d. The Ca concentration is seven times higher than in igneous rocks, but still insignificant for  $\sigma$ . Second,  $\text{CO}_3^{2-}$  can be disregarded, because at Crête the pH averages 5.46 in non-volcanic periods (lower in volcanic periods). The pH corresponds to a background  $\text{HCO}_3^-$  concentration  $[\text{HCO}_3^-]$  of  $1.3 \mu\text{mol kg}^{-1}$ , and  $[\text{H}^+]$  of  $3.5 \mu\text{mol kg}^{-1}$ .

The total anion concentration must of course be balanced by the total cation concentration:

$$[\text{H}^+] + [\text{Na}^+] + [\text{NH}_4^+] = 2[\text{SO}_4^{2-}] + [\text{Cl}^-] + [\text{HCO}_3^-].$$

The  $1.0 \mu\text{mol kg}^{-1}$   $[\text{Na}^+]$  originates from sea salts, which also accounts for the equivalent part of the  $[\text{Cl}^-]$ . Similarly, the  $0.3 \mu\text{mol kg}^{-1}$   $[\text{NH}_4^+]$  may be interpreted as being due to  $(\text{NH}_4)_2\text{SO}_4$  of continental origin, thus accounting for  $0.15 \mu\text{mol kg}^{-1}$   $[\text{SO}_4^{2-}]$ . Subtracting these concentrations, and using the values listed in Table 1, the equation shows an essential balance between the  $3.5 \mu\text{mol kg}^{-1}$   $[\text{H}^+]$  and  $0.8 - 0.15 = 0.65 \mu\text{mol kg}^{-1}$   $[\text{SO}_4^{2-}]$  plus  $0.6 \mu\text{mol kg}^{-1}$   $[\text{Cl}^-]$  plus  $1.27 \mu\text{mol kg}^{-1}$   $[\text{HCO}_3^-]$ , a total corresponding to  $3.2 \mu\text{mol kg}^{-1}$  monovalent anion. Other elements may be present in minor amounts, but according to the above,  $\text{H}_2\text{SO}_4$  contributes 33%,  $\text{CO}_2$ -induced ions 29%,  $\text{HCl}$  15%,  $\text{NaCl}$  8% and  $(\text{NH}_4)_2\text{SO}_4$  3%, a total of 89% of the  $\sigma$  background,  $170 \mu\text{S m}^{-1}$ , at Crête.

Looking at the Laki event as revealed in the Dye 3 ice (Fig. 3) the  $\sigma$  peak value (in part of the mid 1783 layer) is  $\sigma = 1,400 \mu\text{S m}^{-1}$ . The pH is low, corresponding to  $[\text{H}^+] = 33 \mu\text{mol kg}^{-1}$ , and the  $[\text{SO}_4^{2-}]$  amounts to  $12 \mu\text{mol kg}^{-1}$ . Hence, in addition to  $\text{SO}_4^{2-}$ , other anions (probably  $\text{Cl}^-$ , but this is not important here) contribute  $33 - (2 \times 12) = 9 \mu\text{mol kg}^{-1}$ . These concentrations fully account for the measured  $\sigma$  peak value.

The lack of a recent increasing trend of the Crête  $\sigma$  curve (Fig. 2c) suggests that industrial sulphates do not reach Mid Greenland

in appreciable amounts. Other authors<sup>20,22</sup> have drawn the opposite conclusion from North and South Greenland data, showing sulphate concentrations in the period 1964–71 that are roughly twice the concentration in pre-industrial periods. The  $\sigma$  curve in Fig. 2c suggests however, that the Agung eruption 1963 may be responsible for the elevated sulphate (and chlorine) values in the late 1960s, although detailed chemical analyses of a longer and continuous part of the ice cores are needed for firm evidence.

The rise of the excess  $[\text{H}^+]$  in ice layers containing debris from a high northern latitude eruption can be used to roughly estimate the global  $\text{H}^+$  fall-out by applying the same latitudinal distribution pattern as in the case of  $^{90}\text{Sr}$  fall-out from high northern latitude bomb tests. In 1962, the global fall-out of  $^{90}\text{Sr}$  (mainly from the Soviet tests in 1961) was  $1.2 \text{ MCi}$  which was  $8.6 \times 10^8$  times the fall-out per  $\text{km}^2$  at Crête (H. B. Clausen, personal communication). Applying this factor to the fall-out of volcanic  $\text{H}^+$  per  $\text{km}^2$  in 1783 at Crête ( $2.4 \text{ kg km}^{-2}$ ) gives a total fall-out of  $2 \times 10^6$  tons  $\text{H}^+$  during the Laki eruption, or  $100 \times 10^9 \text{ kg}$  of mainly  $\text{H}_2\text{SO}_4$ , as shown in Table 2. Similar estimates can be made for eruptions south of  $50^\circ\text{N}$ , if the  $F$ -factor is accounted for. For example, the Tambora eruption in 1815 seems to have contributed no less than  $300 \times 10^9 \text{ kg}$  of acids to the stratospheric aerosol load. As to the few violent eruptions that have occurred within the period of instrumental observations, the Katmai eruption in 1912 is revealed by a change in  $[\text{H}^+]$  high enough to allow a fairly accurate estimate for comparison with independent estimates. A more detailed  $\sigma$  curve shows that the fall-out from the Katmai eruption lasted approximately 1.5 yr, and the total production of  $\text{H}_2\text{SO}_4 + \text{HX}$  is estimated at  $20 \times 10^9 \text{ kg}$ . This is close to Junge's estimate<sup>6</sup> of  $16 \times 10^9 \text{ kg}$  total mass, suggesting that most of the Katmai aerosols were acids. But, chemical

**Fig. 3** The Icelandic Laki eruption, 1783, revealed in the Dye 3, Crête and Hans Tavsén ice cores by peak values of specific conductivity in melted samples. The Hans Tavsén ice core is not dated absolutely, so the high conductivity layer may very well originate from 1783. The shaded areas show the contribution of hydrogen ions, not induced by  $\text{CO}_2$ .

**Table 2** Estimates of global fall-out of volcanic acids based on pH analyses on the Crête ice core

analyses are needed to reliably assess the magnitude of several medium sized low latitude eruptions (such as Agung, 1963) and to clarify the reasons for the instability of the background in the  $\sigma$  profile. Furthermore, in one case (the Aleutian eruptions 1795 and 1796), the volcanic fall-out had a pH as high as 5.53; consequently, the high  $\sigma$  in this period must be due to high concentrations of other components ((NH<sub>4</sub>)<sub>2</sub>SO<sub>4</sub>, NH<sub>4</sub>Cl?) of relatively low equivalent conductances, which, of course, influences the estimation of the magnitude of these eruptions.

The possible influence of atmospheric turbidity on climate is complicated, because aerosols contribute to the albedo as well as the absorption of radiation. The net-effect upon global temperatures is poorly known. For comparison with climatic records, the  $\sigma$  profile is used to design an objective volcanic aerosol production index (by a procedure opposite to that used to design the v.i.c.i.) and turn it into an index of possible influence of volcanic aerosols upon northern hemisphere temperatures, with due account for the latitudes of the eruptions and for the residence time of the aerosols in the atmosphere. This index has no significant correlation to annual mean temperatures in England<sup>23</sup>, even with time lags up to 10 yr ( $R \sim -0.06$  to  $-0.19$ ;  $P \sim 30$  to  $70\%$ ;  $n = 20$ ), which cannot be due solely to the index being imperfect. The lack of correlation confirms the result of a similar attempt<sup>24</sup> using Lamb's dust veil index. When using 10-yr averages, one finds a high but insignificant correlation ( $R = -0.55$ ,  $P = 93\%$ ,  $n = 8$ ). This procedure is not advisable, because it may mask important time lags. For example, the cooling in the 1960s began several years before the Agung eruption 1963. Other authors<sup>25</sup> have claimed that volcanic aerosols have made important contributions to climatic changes in the past, but they only considered details of the 1884–1970 period that seems to include too few great volcanic events to justify a statistically significant statement.

In conclusion, specific conductivity profiles reveal violent volcanism in the past. Elevated conductivities, due to fall-out of acids, usually allow the contribution of the eruptions to the high altitude aerosol budget to be estimated if the locations of the eruptions are known. If they are unknown, comparison of conductivity profiles along ice cores recovered at different latitudes in Greenland and Antarctica may lead to estimates of the

volcanic activity beyond the range of historical records, at least 10,000 years ago, and particularly when combined with chemical analyses. Ice from the Wisconsin glaciation was deposited in a different climatic regime and contains high and strongly variable amounts of chemical elements<sup>4</sup>, which may complicate the interpretation. One way of using long volcanic activity records would be to check if they have any relation to climatic changes as revealed by stable isotope profiles along the same cores. Another aspect concerns the high concentrations of hydrogen ions in layers deposited in periods of high volcanic activity, which suggests anomalous dielectric properties of such ice. Series of layers containing high concentrations of volcanic impurities is, therefore, a possible explanation of the internal reflection layers encountered in radio-echo sounding<sup>26</sup>.

I thank Professors W. Dansgaard and C. Junge for valuable suggestions. The work was supported through funds provided by the Ministry of Greenland and the Danish Natural Science Research Council.

## Nucleotide sequence and amplification in bacteria of structural gene for rat growth hormone

Peter H. Seeburg, John Shine, Joseph A. Martial, John D. Baxter & Howard M. Goodman

Department of Biochemistry and Biophysics and Metabolic Research Unit, University of California, San Francisco, California 94143

*The primary structure of DNA containing the sequence for rat pituitary growth hormone mRNA has been determined. DNA was obtained by reverse transcription of polyadenylated RNA from cultured pituitary cells and from recombinant bacterial plasmids. The amino acid sequences for rat growth hormone and its precursor form have been deduced from the determined nucleotide sequences.*

SOMATOTROPIN (growth hormone, GH) is essential for linear growth in man and other vertebrates. In childhood, deficiency of this peptide hormone results in dwarfism whereas overproduction causes gigantism. In the adult, pathological overproduction of growth hormone can lead to acromegalic deformations<sup>1,2</sup>. Somatotropin is separable in activity and substance from the related pituitary hormone prolactin<sup>3,4</sup>. Comparisons of primary structures have revealed that these hormones, together with the placental hormone chorionic somatomammotropin form a group of sequence-related peptides of molecular weights (MW) around

22,000, with a suggested common evolutionary origin<sup>5-7</sup>. The three hormones also share certain features in their biological actions<sup>8</sup>.

The genes for somatotropin and related hormones thus provide an excellent system for studying structure, evolution and regulation of a set of similar DNA sequences whose expression is ordinarily confined to separate tissues (pituitary and placenta) and is elicited by different physiological stimuli. While information on the structural gene for human chorionic somatomammotropin has very recently been obtained by us<sup>9,10</sup>, no such information has been available for growth hormone.

We report here the *in vitro* synthesis, determination of the nucleotide sequence, and the amplification in bacteria of structural gene sequences for growth hormone starting with mRNA from cultured rat pituitary cells<sup>11</sup>. These cells can be hormonally induced to produce and secrete somatotropin<sup>12,13</sup>. In analogy to other secreted proteins, synthesis of this peptide occurs at the rough endoplasmic reticulum as a precursor form<sup>14-16</sup>. The N-terminal portion (signal peptide) of the precursor is thought to be involved in the attachment of ribosomes to membranes, a process essential for hormone maturation and secretion (for model on mechanism see ref. 17). Accordingly, the primary translation product of rat growth hormone mRNA is a peptide larger (by about 3,000 MW units, see Fig. 1) than the mature hormone<sup>13,16</sup>. As the primary structure of rat somatotropin is only partially known<sup>18</sup>, the nucleotide sequence determined for the mRNA allows us to predict the complete amino acid sequence of the hormone including the previously unknown sequence of the signal peptide.

### Detection and sequence determination of DNA complementary to growth hormone mRNA

Certain tissues in which the mRNA for a specialised function represents a large proportion of the polyadenylated RNA (for example, globin RNA in reticulocytes<sup>19</sup>, ovalbumin RNA in induced oviducts<sup>20</sup>, insulin RNA in the islets of Langerhans<sup>21,22</sup>) allow for their convenient detection and characterisation of such RNAs or their cDNAs. In cultured rat pituitary cells (strain GC), however, when grown in normal conditions, growth hormone mRNA represents only a small percentage (1-3%) of the total poly A containing RNA<sup>13</sup>. Therefore, the detection and isolation of nucleic acid sequences specific for rat growth hormone were approached by a strategy previously used to obtain sequences from polyadenylated RNAs that constitute 2% or more of the cellular messengers<sup>9</sup>. This strategy involves restriction endonucleolytic cleavage of complex cDNA mixtures (single or double stranded) prepared by reverse transcription of polyadenylated cellular RNAs, followed by gel electrophoretic separation of the resultant cDNA fragments. In applying this approach to the detection of growth hormone cDNA we were aided by the fact that in cultured rat pituitary cells growth hormone mRNA levels can be raised above that of other cellular mRNA species by the synergistic action of thyroid hormones and glucocorticoids<sup>13,23</sup>. Further enrichment of growth hormone mRNA was achieved by isolating poly A-containing RNA from cytoplasmic membranes<sup>24</sup> where growth hormone is synthesised. In the final RNA template used for cDNA synthesis, growth hormone mRNA was therefore the most abundant species representing about 10% of the RNA (see Fig. 1).

Analysis by gel electrophoresis of this cDNA after cleavage with endonucleases *Hae*III and *Hha*I is shown in Fig. 2. Each enzyme generates several abundant DNA fragments which can be seen as prominent bands above the polydisperse background of the restricted cDNA. Whereas *Hae*III yields a complex fragment pattern (Fig. 2b), cleavage with *Hha*I produces a simpler pattern characterised by two major DNA fragments, approximately 320 (fragment A) and 240 (fragment B) nucleotides long (Fig. 2c). The prominence of fragments A and B suggests that they may be derived from growth hormone mRNA.

For further characterisation, these fragments were isolated from a polyacrylamide gel on which approximately 1  $\mu$ g of *Hha*I-

**Fig. 1** Translation products of rat growth hormone mRNA. Polyadenylated RNA was isolated from the cytoplasmic membrane fraction of cultured rat pituitary cells (strain GC) as described elsewhere<sup>13,24</sup>. Usually, 30  $\mu$ g of poly A-containing RNA were obtained from  $5 \times 10^8$  cells grown in suspension culture and induced for GH production by including 1  $\mu$ M dexamethasone and 10 nM L-triiodothyronine in the medium for 4 d before cell collection. Polyadenylated RNA was also isolated from cells grown for 4 d in the absence of dexamethasone and triiodothyronine<sup>23</sup>. Aliquots of these RNA preparations (500 ng) were translated in a cell-free translation system derived from wheat germ, and the products immune-precipitated using rhesus monkey antiserum to rat GH as previously described<sup>13</sup>. To obtain labelled rat growth hormone, induced cells (about  $10^6$  cells in 1 ml) were pelleted, resuspended in 0.2 ml of serum- and methionine-free medium containing bovine serum albumin (0.5  $\mu$ g ml<sup>-1</sup>), and labelling was carried out with <sup>35</sup>S-methionine (50  $\mu$ Ci, NEN) for 4 h at 37 °C. Cells were pelleted and labelled rat GH released into the medium was immune-precipitated as described above. Protein products of cell-free translations and immunoprecipitations were separated in 12.5% polyacrylamide slab gels (14  $\times$  14  $\times$  0.2 cm) in the presence of sodium dodecylsulphate<sup>26</sup> at 20 mA per gel for 4 h. Gels were soaked in 50% trichloroacetic acid, washed in 7% acetic acid, dried on paper (Whatman 3MM), and exposed to X-ray film (Kodak NS2T). The autoradiogram shown contains a, translation products of poly A 'membrane' RNA from cells grown in the absence of dexamethasone and thyroid hormone; b, the same as (a) except that the RNA was isolated from hormone-induced cells; c, immune-precipitate of (b); d, immune-precipitate of secreted rat GH; e, <sup>14</sup>C-labelled proteins from bacteriophage T4-infected *E. coli* cells<sup>27</sup> as size markers.

restricted cDNA had been separated. Each fragment was further cleaved by *Hae*III (see Fig. 2c) and the products (A<sub>1</sub> ~ 180, A<sub>2</sub> ~ 75, A<sub>3</sub> ~ 65, B<sub>1</sub> ~ 140, B<sub>2</sub> ~ 100 nucleotides) enzymatically labelled with <sup>32</sup>P at their 5' termini. Following gel electrophoretic separation, the five labelled DNA fragments were processed for nucleotide sequence determination according to

**Fig. 2** Restriction endonuclease cleavage of single-stranded cDNA to rat pituitary cell RNA. Aliquots (300 ng) of the polyadenylated RNA prepared as described in Fig. 1, were transcribed into cDNA in 5- $\mu$ l reactions containing 50 ng oligo-dT<sub>12-18</sub> (Collaborative Research), 50 mM Tris-HCl, pH 8.1, 20 mM KCl, 7 mM MgCl<sub>2</sub>, 0.1 mM EDTA, 10 mM  $\beta$ -mercaptoethanol, 500  $\mu$ M each of dGTP, dCTP, dTTP, 30  $\mu$ M  $\alpha$ -<sup>32</sup>PdATP (specific activity  $5 \times 10^4$  c.p.m. pmol<sup>-1</sup>), and 5 U reverse transcriptase. DNA synthesis proceeded for 7 min at 42 °C and incorporation of <sup>32</sup>P-dAMP into DNA was approximately  $2 \times 10^6$  c.p.m. Reaction mixtures were diluted with 20  $\mu$ l of H<sub>2</sub>O, heated to 95 °C for 2 min, quick-cooled, adjusted to 7 mM MgCl<sub>2</sub>, and split into 5  $\mu$ l aliquots for restriction endonuclease cleavage of cDNA. Digestion with *Hae*III (2 U), or *Hha*I (2 U), or both enzymes<sup>9</sup> was for 60 min at 37 °C. Mixtures were made 10 mM in EDTA, 10% in sucrose, 0.2% in sarcosyl, 0.05% in bromophenol blue (final volume 10  $\mu$ l), heated to 95 °C for 2 min, quick-cooled, loaded on to 4.5% polyacrylamide slab gels (14  $\times$  14  $\times$  0.2 cm) in TBE buffer<sup>58</sup>, and electrophoresed at 150 V for 2 h. Gels were dried and exposed to X-ray film (Kodak NS2T). The autoradiogram shown (obtained after 4 h of exposure) contains a, uncleaved cDNA; b, *Hae*III-cleaved cDNA; c, *Hha*I-cleaved cDNA; d, cDNA cleaved with *Hae*III and *Hha*I; e, *Hae*III-cleaved <sup>32</sup>P-labelled phage M13 single-stranded DNA<sup>59</sup> as molecular weight marker. Numbers indicate approximate sizes in nucleotides.

Maxam and Gilbert<sup>25</sup>. Typical examples of such determinations are shown in Fig. 3, and the nucleotide sequences are compiled in Fig. 7.

To identify their origin, the cDNA sequences were converted into their antiparallel complementary RNA sequences and the coding potential in the three possible phases was compared with the known amino acid sequences of several vertebrate GHs<sup>26</sup>, including parts of rat growth hormone determined by Wallis and Davies<sup>18</sup>. This comparison showed that cDNA fragments A and B clearly originate from rat growth hormone mRNA. This result emphasises the experimental advantage of analysing DNA reverse transcribed from complex cellular RNA mixtures for

obtaining primary structural information on abundant mRNA species.

Fragments A and B are complementary to a contiguous segment of the mRNA, extending from the codon for amino acid 149 to approximately 40 nucleotides to the 5' side of the AUG initiation codon for pre-growth hormone (see Fig. 8). Since the distance of some 40 nucleotides from the end of fragment B to the initiation codon for pre-growth hormone (see Fig. 8). As the region in other eukaryotic mRNAs<sup>27,28</sup>, it is possible that the 3' terminus of fragment B corresponds to the 5' terminus of the mRNA, and is not generated by *Hha*I cleavage (see also later).

### Molecular cloning of growth hormone structural gene sequences

To obtain a convenient source of growth hormone DNA for further analyses, we constructed bacterial plasmids containing the structural gene for rat growth hormone. The cDNA fragments A and B served as excellent markers for monitoring construction of the correct plasmids. The starting material for the *in vitro* synthesis and subsequent cloning of the structural gene sequences was a cDNA preparation comparable in amount and purity to the one used for sequencing fragments A and B. By using its self-priming properties, this cDNA was enzymatically converted to its duplex form characterised by a hair-pin structure on one end and a poly(dA-dT) tract on the other<sup>29</sup>. S1 nuclease was used to open the terminal hair-pin loop and to degrade any single-stranded DNA. Gel analysis of the DNA material before and after nuclease treatment (Fig. 4b, c) demonstrates the presence of a double-stranded DNA of approximately 800 base pairs faintly detectable above the disperse background of other DNA. An aliquot of this DNA species was purified by gel electrophoresis and cleaved with *Hha*I. Two prominent fragments corresponding in size to DNA fragments A and B were among the major cleavage products (see Fig. 4i). As fragment B is complementary to the 5' portion of growth hormone mRNA (see above), this finding indicated that the 800-base pair DNA contained primarily full-length copies of the messenger.

To allow for reversible insertion into a bacterial cloning vehicle, the double-stranded cDNA was given cohesive ends by enzymatic blunt-end ligation<sup>30</sup> to chemically-synthesised restriction site linkers, and subsequent cleavage with the appropriate restriction endonuclease<sup>31,32</sup>. The linkers had the self-complementary sequence 5'-CCAAGCTTGG-3', containing the recognition site for *Hind*III. This site is not present in the 800-base pair DNA (data not shown) and occurs once in the bacterial plasmid pBR322 chosen for cDNA insertion (see below). Preceding ligation to linkers, the S1 nuclease-treated double-stranded cDNAs were 'blunt-ended' using *Escherichia coli* DNA polymerase I in the presence of deoxynucleoside triphosphates<sup>33</sup> (see legend to Fig. 4). This step ensured a high participation of the cDNA molecules in the ligation reaction, as shown by the blurred appearance due to multiple linker additions, of both the 800-base pair DNA and DNA fragments A and B (see Fig. 4d, f). Fragments A and B had been obtained by *Hha*I-cleavage of the double-stranded cDNA before S1-treatment and their 3'-CG ends removed by *E. coli* DNA polymerase I before linker attachment. The ligation products were cleaved with *Hind*III (*Hsu*I endonuclease was used interchangeably with *Hind*III) to generate DNA molecules with cohesive termini and to digest self-ligated linkers (Fig. 4e, g). The 800-base pair DNA and DNA fragments A and B were purified on a polyacrylamide gel (Fig. 4h, k) to reduce the level of DNA sequences unrelated to growth hormone that would enter the bacterial cells.

The EK-2 vector pBR 322<sup>34</sup>, a relaxed replicating plasmid of MW  $2.6 \times 10^6$  containing a single *Hind*III cleavage site was used as the cloning vehicle for growth hormone cDNA. Before insertion of the cDNA, the *Hind*III-cleaved linear plasmid was treated with bacterial alkaline phosphatase to remove the 5'-terminal phosphate groups. This step permits the selective construction of recombinant plasmids by preventing closure of the plasmid at the original cleavage site. Infectious circular plasmid forms will only be generated by bridging and closing the plasmid

**Fig. 3.** Autoradiograms of 20% polyacrylamide, 7 M urea gels used for sequence analysis of *a*, cDNA fragment A<sub>1</sub> (nucleotide 522 to 340, see Fig. 7), starting at nucleotide 519; *b*, cDNA fragment B<sub>2</sub> (60 to about -40), starting at nucleotide 53; *c*, 5' terminal *AluI* fragment (-22 to 144) of pRGH-1, starting at nucleotide -18; *d*, *HaeIII* fragment (61 to 274) of pRGH-1, starting at nucleotide 63. The labelled DNA fragments were recovered from polyacrylamide slab gels (see below) and subjected to the described procedure for nucleotide sequence analysis<sup>2,5</sup>. G, A, T, C refer to the respective base specific cleavages. The nucleotide sequence can be read directly from the gel as shown for the 5' portion of each sequence fragment. Single-stranded cDNA for nucleotide sequence analysis was prepared from polyadenylated RNA as described in the legend to Fig. 2, except that the reaction (200 µl) contained 15 µg of RNA, 2 µg of oligo dT<sub>12-18</sub>, 800 µM each of dGTP, dCTP, dTTP, and 400 µM of α-<sup>32</sup>P-dATP (specific activity 500 c.p.m. pmol<sup>-1</sup>). Synthesis proceeded for 10 min at 42 °C (incorporation of <sup>32</sup>P-dAMP into cDNA was about 5 × 10<sup>5</sup> c.p.m.), and was stopped by addition of EDTA to 10 mM. Reaction mixtures were phenolised and the nucleic acid precipitated with ethanol. Pellets were then dissolved in 100 µl of Tris-HCl, pH 7.5, 0.01 mM EDTA, 40 mM NaCl, 5 mM β-mercaptoethanol, heated to 95 °C for 5 min, quick-cooled, and adjusted to 7 mM MgCl<sub>2</sub>. After addition of *HhaI* (20 U) digestion proceeded for 2 h at 37 °C, followed by incubation with 0.2 U of bacterial alkaline phosphatase (BAPE, Worthington) for 10 min at 65 °C. Reaction mixtures were phenolised, DNA precipitated with ethanol, redissolved in 25 µl of 5 mM Tris-HCl, pH 7.5, 1 mM EDTA, 10% sucrose, 0.05% bromophenol blue, and separated on 6% polyacrylamide slab gels in TBE buffer<sup>58</sup> for 2 h at 150 V. cDNA fragments were visualised by exposing the wet gels to X-ray film (Kodak, NS2T) for 3 h. Gel bands containing cDNA fragments A and B were excised, DNA was eluted overnight from the crushed gel material<sup>2,5</sup> and precipitated with ethanol. The recovered fragments were cleaved with *HaeIII* (5 U per fragment) at 37 °C for 2 h in 20 µl of 10 mM Tris-HCl, pH 7.5, 8 mM MgCl<sub>2</sub>. After inactivation of *HaeIII* at 80 °C for 5 min, the DNA fragments were terminally labelled by adjusting the digestion mixtures to 50 mM Tris-HCl, pH 8.5, 10 mM MgCl<sub>2</sub>, 0.1 mM spermidine, 5 mM β-mercaptoethanol, 5% glycerol, 500 µCi γ-<sup>32</sup>P-ATP (specific activity 1.5 µCi pmol<sup>-1</sup>), and 5 U of T4 polynucleotide kinase at 37 °C for 2 h (final volume 40 µl). Following phenol extraction, the DNA was precipitated with ethanol, dissolved in 25 µl of mM Tris-HCl, pH 7.5, 1 mM EDTA, 10% sucrose, 0.05% bromophenol blue, and separated by electrophoresis in 8% polyacrylamide slab gels. cDNA fragments were visualised by autoradiography of the wet gels (exposure time about 10–20 min), excised and eluted from the gels, precipitated with ethanol, and processed directly for nucleotide sequence determination<sup>2,5</sup>. For nucleotide sequence analysis of pRGH-1 DNA an appropriate amount (5–30 µg) of the isolated 800-base pair DNA insert was cleaved with one, or a combination, of the restriction endonucleases *HaeIII*, *HhaI*, *AluI*, *HpaII*, *KpnI* or *PstI* (see Fig. 6). After 5'-terminal enzymatic labelling (see above) fragments (isolated individually or in a mixture) were additionally cleaved with one of the enzymes listed above, and products were separated by polyacrylamide slab gel electrophoresis. In cases where a DNA fragment labelled at both 5' termini could not be cleaved by one of the enzymes listed above, the two strands of that fragment were separated on a 8% polyacrylamide slab gel in TBE buffer, after loading in 0.2 M NaOH, 1 mM EDTA<sup>2,5</sup>.

Following ligation of the gel-isolated 800-base pair DNA to phosphatase-treated linear pBR322 plasmid the reaction mixture

(see above). Fractions containing DNA were pooled and the nucleic acid precipitated with ethanol. The precipitate was redissolved in 100  $\mu$ l of 5 mM Tris-HCl, pH 7.5, 0.05 mM EDTA, and split into 50  $\mu$ l aliquots. One aliquot was adjusted to 300 mM NaCl, 30 mM Na-acetate, pH 4.5, 3 mM ZnCl<sub>2</sub>, and incubated with 5 U of S1 nuclease (prepared according to Vogt<sup>60</sup>) at 37 °C for 10 min followed by phenol extraction in the presence of 5 mM EDTA and precipitation of the DNA with ethanol. The second aliquot was adjusted to 10 mM Tris-HCl, pH 7.5, 30 mM NaCl, 8 mM MgCl<sub>2</sub>, 5 mM  $\beta$ -mercaptoethanol, and the DNA was cleaved with 5 U of *Hha*I for 2 h at 37 °C followed by phenol extraction and precipitation of the DNA fragments with ethanol. For ligation to the *Hind*III linkers, DNA precipitates from both aliquots were separately dissolved in 25  $\mu$ l of 60 mM Tris-HCl, pH 7.5, 8 mM MgCl<sub>2</sub>, 10 mM  $\beta$ -mercaptoethanol, 1 mM ATP, and 200  $\mu$ M each of dATP, dTTP, dGTP, dCTP. They were incubated with 1 U (1  $\mu$ l) of *E. coli* DNA polymerase I at 10 °C for 10 min to exonucleolytically remove any 3' protruding ends and to 'fill in' any 5' protruding ends<sup>33</sup>. Incubation was followed by addition of 50 pmol of 5' <sup>32</sup>P-labelled *Hind*III linker (10<sup>5</sup> c.p.m. pmol<sup>-1</sup>, in 15  $\mu$ l of 60 mM Tris-HCl, pH 7.5, 8 mM MgCl<sub>2</sub>, 10 mM  $\beta$ -mercaptoethanol, 1 mM ATP), and bacteriophage T4 DNA ligase (to 20  $\mu$ g ml<sup>-1</sup>)<sup>61</sup>. Ligation was for 60 min at 20 °C. Reaction mixtures were diluted with 100  $\mu$ l of 7 mM MgCl<sub>2</sub>, 50 mM NaCl, heated at 80 °C for 5 min, cooled and DNA digested with 15 U of *Hsu*I at 37 °C for 4 h. The reaction mixtures were phenolised, DNA was precipitated with ethanol, redissolved in 25  $\mu$ l of 5 mM Tris-HCl, pH 7.5, 1 mM EDTA, 10% sucrose, 0.05% bromophenol blue, and separated on 4.5% polyacrylamide slab gel at 150 V for 2 h. The 800-base pair DNA and the double-stranded rat GH DNA fragments A and B were visualised by autoradiography of the wet gel and electrophoretically eluted from the isolated gel pieces. Lanes a and l, *Hpa*II-cleaved <sup>32</sup>P-labelled phage M13 RF DNA<sup>62</sup> as molecular weight marker (numbers indicate approximate sizes in base pairs); b, DNA product after second strand synthesis; c, S1 nuclease digest of the sample shown in b; d, *E. coli* DNA polymerase I treatment and ligation of *Hind*III linkers to the sample shown in c; e, digestion of sample d with *Hsu*I; f, double-stranded cDNA cleaved with *Hha*I, blunt-ended with *E. coli* DNA polymerase I, and ligated to *Hind*III linkers; g, *Hsu*I cleavage of the sample shown in f; h 800-base pair DNA with cohesive *Hind*III termini after preparative gel elution; i, *Hha*I digestion of the gel-eluted 800-base pair DNA; k, double-stranded DNA fragment A with cohesive *Hind*III termini after preparative gel elution.

tetracycline resistance<sup>34</sup>. Recombinants were therefore selected by growth on nutrient plates containing ampicillin, and by their inability to grow on high levels (20  $\mu$ g ml<sup>-1</sup>) of tetracycline. Ten colonies were obtained which all carried plasmid with an insert of approximately 800 base pairs that was released by *Hind*III cleavage. Consistent with the purity of the cDNA material inserted into plasmid (30–50% growth hormone DNA, see Fig. 4i), 4 of the 10 inserts were growth hormone DNA as judged by their restriction endonuclease patterns (Figs 5 and 6), and shown by direct sequencing in one case (see below).

Growth hormone DNA fragment A was successfully cloned in the same manner: 7 out of 8 clones contained plasmid with the correct DNA insertion as seen by *Hae*III and *Kpn*I digestion (see Fig. 6). Nucleotide sequence analysis of one of these inserts showed that the 3' protruding –CG termini in the double-stranded cDNA fragment A had been removed correctly by *E. coli* DNA polymerase I (see Fig. 7) demonstrating the reliability of this method for obtaining defined blunt-ended DNA molecules from those with frayed ends. No clones were obtained for DNA fragment B. This could reflect the finding (see below) that the cloned 800-base pair DNA does not contain the presumptive *Hha*I-site which was thought to terminate the single-stranded cDNA fragment B. The double-stranded form of this fragment probably retained its terminal hairpin after *Hha*I cleavage, thereby preventing the addition of linkers to this end of the molecule and its subsequent insertion into the cloning vehicle.

### Sequence determination of the cloned DNA

The 800-base pair growth hormone DNA was isolated in preparative amounts from one of the recombinant clones (pRGH-1) and its nucleotide sequence determined by the method of Maxam and Gilbert<sup>25</sup> (see Fig. 3b). The entire sequence of this DNA is compiled in Fig. 7. A large part of it has been confirmed by determining the nucleotide order in both DNA strands. The sequence is identical to that determined for cDNA fragments A and B which demonstrates the fidelity of amplifying eukaryotic

Fig. 4 Preparation of double-stranded cDNA from rat growth hormone mRNA. Polyadenylated pituitary cell RNA (15  $\mu$ g) was reverse-transcribed into cDNA as detailed in Fig. 3. Synthesis was stopped by addition of EDTA to 10 mM, the reaction mixture phenolised and nucleic acid precipitated with ethanol. The precipitate was redissolved in 75  $\mu$ l of 5 mM Tris-HCl, pH 7.5, 1 mM EDTA, fractionated on a Sephadex G-50 column (0.6  $\times$  10 cm) in the same buffer, and fractions containing the cDNA were pooled. After precipitation with ethanol nucleic acid was redissolved in 150  $\mu$ l of 0.1 N NaOH, 1 mM EDTA, and the RNA hydrolysed at 70 °C for 20 min. After neutralisation and precipitation with ethanol, the single-stranded cDNA was converted to its duplex form in a 50- $\mu$ l reaction containing 50 mM Tris-HCl, pH 8.1, 0.1 mM EDTA, 20 mM KCl, 7 mM MgCl<sub>2</sub>, 10 mM  $\beta$ -mercaptoethanol, 400  $\mu$ M each of dGTP, dTTP, dCTP, and 100  $\mu$ M of  $\alpha$ -<sup>32</sup>P dATP (specific activity about 10<sup>4</sup> c.p.m. pmol<sup>-1</sup>). The reaction mixture was heated to 90 °C for 2 min, quick-cooled, and synthesis proceeded for 2 h at 40 °C (incorporation of <sup>32</sup>P-dAMP into DNA was approximately 3  $\times$  10<sup>6</sup> c.p.m.) followed by addition of 2  $\mu$ g of *E. coli* tRNA, phenol extraction, and fractionation of the aqueous phase by gel filtration

structural gene sequences in bacteria, and stresses the advantage of cDNA sequencing to probe such fidelity.

The cloned 800-base pair DNA specifies the entire coding sequence for the precursor form of rat growth hormone. In addition, it contains all of the 3', and part of the 5' untranslated region of growth hormone mRNA. Failure to obtain the complete 5'-terminal sequence of a mRNA in cloned double-stranded cDNA (synthesised *in vitro* by self-priming of single-stranded cDNA and S1 nuclease treatment) has also been observed in the few other instances reported<sup>22,35</sup>.

### Primary structure of rat growth hormone mRNA

The DNA sequence determined from cDNA and cloned material allows us to derive the primary structure of rat growth hormone mRNA as shown in Fig. 8. The size of this RNA (excluding the poly A) is estimated to be 800 nucleotides, assuming that the 5' end corresponds approximately to the 3' end of cDNA fragment B. This estimate agrees well with previous values obtained from velocity sedimentation<sup>13</sup> and gel electrophoresis<sup>36</sup> of rat growth hormone mRNA.

Only preliminary conclusions can be drawn about the 5'-untranslated part of growth hormone RNA since the full sequence has not yet been established. At least 20 nucleotides are known to be missing from pRGH-1, but a tentative sequence is available from cDNA fragment B (Fig. 7).

No obvious features characterise the established 5' portion of the mRNA sequence and no apparent homology to known 5' untranslated regions of other eukaryotic messengers is found. But, there is a potential complementarity with the 3' terminal sequence (5'-GAUCAUUA-3') of eukaryotic 18S ribosomal RNA involving nucleotides –15 to –12 in the messenger. An interaction between the 5' end of mRNA and the 3' end of ribosomal RNA has been demonstrated in the initiation of translation for prokaryotic mRNAs<sup>37,38</sup>, and by analogy has been suggested to occur in eukaryotes<sup>39</sup>. The linear distance from this site to the initiation codon AUG is comparable with that in rabbit  $\beta$ -globin RNA<sup>27,40</sup> and rous sarcoma viral RNA<sup>28</sup> where

such a complementarity has also been observed.

It may be of interest that the region surrounding the AUG initiation codon can be folded into a secondary structure with the AUG being part of a hairpin loop (residues -4 to 3) and the base-paired stem interrupted by non-complementary sequences (residues -17 to -11, and 11 to 20) containing the region complementary to the 3' terminus of 18S ribosomal RNA. Such a structure ( $T_m$  approximately 50 °C) could form through interaction with proteins involved in the initiation of protein synthesis.

The 3' untranslated region of rat GH mRNA contains 105 nucleotides, excluding the poly A. Whereas the distal portion of this region is rich (73%) in A+U, 30 of the first 64 nucleotides following the UAG termination codon are C's, present mainly in stretches of 4, 5, or 6 residues. Two of these C tracts are part of a sequence of 16 pyrimidines (residues 676-693) interrupted around the centre by two purines. Such highly asymmetric distribution of purines and pyrimidines is known to influence the secondary structure of the corresponding DNA double helix<sup>42</sup> and may be of significance concerning structural requirements for transcriptional regulation. It is interesting to note that the CCACCCU sequence (nucleotides 709-716) found at the end of the C-rich region is also present in rat insulin mRNA<sup>22</sup>, and slightly modified in human  $\alpha$ -globin<sup>43</sup> and rabbit  $\beta$ -globin RNA<sup>44</sup>.

Several regions with symmetry elements occur throughout the 3'-terminal sequence of GH mRNA. Of note are four regions of a palindromic nature the first two of which (following the termination codon) overlap in sequence comprising 12 and 20 nucleotides and are centred around positions 656 and 667 respectively. The third region surrounds the GUUA sequence (residues 683-686) with two C tracts, and is reminiscent of the extended palindrome found in an equivalent position in HCS mRNA<sup>9,10</sup>. The fourth palindrome (nucleotides 728-740) is solely composed of A and U residues and contains the AAUAAA stretch found in all other eukaryotic mRNAs sequenced to date<sup>45</sup>. Between this sequence and the poly A tract a self-complementary sequence occurs (nucleotides 739-750) which would form a region of twofold symmetry in the corresponding double-stranded DNA. The functions of these symmetry elements and sequence features are unknown. These sequences may be of regulatory nature providing sites of interaction with proteins involved in the transcription of the growth hormone gene, and in the processing, packaging, and translation of growth hormone mRNA.

The poly A tract characteristic of most eukaryotic mRNAs<sup>46</sup> starts with nucleotide 754. As determined from the cloned DNA sequence this tract is interrupted after 10 nucleotides by a C residue. This finding probably reflects the slippage of the extended oligo-dT primer in the initial stages of cDNA synthesis. But, the existence of occasional substitutions in poly A tracts of mRNAs cannot be excluded.

**Fig. 5** Restriction endonuclease cleavage pattern of cloned 800-base pair rat growth hormone DNA. The 800-base pair DNA and DNA fragments A and B, purified by gel electrophoresis, were ligated to the EK-2 vector pBR 322<sup>34</sup> in 50- $\mu$ l reactions containing 60 mM Tris-HCl, pH 8, 10 mM  $\beta$ -mercaptoethanol, 8 mM MgCl<sub>2</sub>, between 10 and 50 ng (as judged from their specific activities) of the purified DNAs, and approximately 500 ng of *Hind*III-cleaved 5'-dephosphorylated plasmid DNA. Ligations were started by addition of T4 DNA ligase (to 5  $\mu$ g ml<sup>-1</sup>)<sup>61</sup>, allowed to proceed at 15 °C for 1 h, and mixtures diluted to 0.25 ml with 120 mM NaCl, 1 mM EDTA. The NIH-certified EK-2 host *E. coli* X1776 constructed by R. Curtiss III was grown in 150 ml of nutrient broth supplemented with DL- $\alpha$ -diaminopimelic acid (DAP, 100  $\mu$ g ml<sup>-1</sup>) and thymine (40  $\mu$ g ml<sup>-1</sup>) to an  $A_{650}$  of 0.2. After centrifugation the cells were washed in 60 ml of 10 mM NaCl, pelleted, resuspended in 60 ml of transformation buffer (10 mM Tris-HCl, pH 8, 140 mM NaCl, 75 mM CaCl<sub>2</sub>), kept on ice for 15 min, pelleted, and resuspended in 1.5 ml of the same buffer. The following transformation, cell growth, and the isolation of cloned, recombinant plasmid DNA were performed in a certified P3 laboratory. After adding 0.5 ml of CaCl<sub>2</sub>-treated cells to the diluted ligation reactions the transformation mixtures (0.75 ml) were kept on ice for 15 min, at 25 °C for 4 min, and again on ice for 30 min. They were then plated directly on to nutrient plates (about 0.2 ml per plate) containing ampicillin (20  $\mu$ g ml<sup>-1</sup>), DAP (100  $\mu$ g ml<sup>-1</sup>), and thymine (40  $\mu$ g ml<sup>-1</sup>) and the plates incubated for 24 h at 37 °C. In these conditions about 20 transformants were usually obtained from each ng of supercoiled pBR 322 plasmid. In the experiments described here transformation with the 800-base pair DNA yielded 11 colonies, one of which grew on tetracycline (20  $\mu$ g ml<sup>-1</sup>) and carried plasmid without insert. cDNA fragment preparations A and B gave 8 and 5 colonies, respectively. Analysis of the isolated plasmids by restriction endonuclease cleavage and 6% polyacrylamide slab gel electrophoresis of the cleavage products (which were then visualised under ultraviolet light after staining with ethidium bromide<sup>66</sup>) showed that 4 colonies contained 800-base pair GH DNA, 7 colonies contained GH DNA fragment A and none was found to contain GH fragment B. Shown are digests of pRGH-1 insert (800-base pair rat GH DNA) with the restriction endonucleases: *Hae*III and *Pst*I, (b); *Hae*III, (c); *Hha*I, (d); *Hha*I and *Kpn*I (e); *Alu*I (f); *Alu*I and *Hpa*II (g); no enzyme (h). Lanes (a) and (i) contain *Hpa*II-cleaved phage fd-RF DNA<sup>62</sup> as molecular weight marker. Numbers indicate approximate sizes in base pairs.

**Fig. 6** Physical map of rat growth hormone mRNA from the poly A to the 5' end. The black and white boxes span the coding region and represent the signal region and the region coding for the mature hormone respectively. Characteristic amino acids and their respective positions are shown above the boxed areas for orientation. The locations of the cleavage sites in the corresponding DNA for restriction endonucleases *Alu*I, *Hae*III, *Hha*I, *Hpa*II, *Kpn*I, and *Pst*I were determined from growth hormone cDNA and from cloned growth hormone DNA. It is uncertain whether the left-most *Hha*I site exists or whether this site represents the 5' end of growth hormone mRNA. The segments comprised by cDNA fragments A and B, and by the cloned fragments present in pRGH-1 and pRGH-2 are indicated. Nucleotide numbers are given below the symbols for the endonucleases.

**Fig. 7** Nucleotide sequence of the structural gene for rat growth hormone. The sequences shown were determined by the method of Maxam and Gilbert<sup>25</sup> from fragments of single-stranded cDNA to rat growth hormone mRNA and from the recombinant bacterial plasmids pRGH-1 and pRGH-2 (see Fig. 3). Also shown are the locations of restriction endonuclease sites used for cleaving cDNA and cloned DNAs. The sequences obtained from the single-stranded cDNA fragments, A<sub>1</sub>, A<sub>2</sub>, A<sub>3</sub>, B<sub>1</sub>, and B<sub>2</sub> are in italics and span residues 521–421, 272–202, 337–276, 196–110, and 58 to –37 respectively. (Position 1 is assigned to the A residue in the AUG initiator for the precursor protein.) The cDNA sequence in parentheses is not fully confirmed. Sequences obtained from cloned DNAs are shown in bold type. The second C residue in the sequence CC<sup>1</sup>AGG appears as a gap in the sequencing gels due to methylation<sup>63</sup> in *E. coli* X1776. The presence of this nucleotide inferred from band spacings was confirmed from the sequence of the complementary strand or the cDNA. Nucleotides 523–525 were not directly sequenced but inferred from the existence of the *Hha*I site in this position. The boxed sequences represent the cohesive termini derived from the *Hind*III linkers and mark the ends of pRGH-1 and pRGH-2.

The coding region contains 648 nucleotides which specify the 216 amino acids of the growth hormone precursor. The codon choices are listed in Table 1. It can be seen that codon utilisation is distinctly non-random, a phenomenon also noted in the coding sequences of other eukaryotic<sup>9,10,22,40</sup> and prokaryotic<sup>47,48</sup> mRNAs. As a consequence of such selective codon usage, growth hormone mRNA has a high G + C content (57.7%) which exceeds that of total rat DNA (43%)<sup>49</sup>.

### Amino acid sequence of rat pre-growth hormone

The established mRNA sequence permits the prediction of the complete amino acid sequence of the proposed physiological precursor form of rat growth hormone (pre-GH). The amino acid composition of this protein is given in Table 1.

The signal peptide of pre-GH (26 amino acids, MW 2,846) has a high content of hydrophobic amino acids (17 non-polar residues,

The amino acid sequence of rat pre-growth hormone has been solely predicted from the nucleotide sequence of rat growth hormone mRNA (see Fig. 8). Numbers next to codons indicate the number of amino acids using particular codons in the mature hormone, numbers in parentheses denote the extra amino acids of the pre-part. The N-terminal methionine is included. From a total of 216 codons used, 39.4% terminate in C, 34.3% in G, 18% in U, and 8.3% in A. The molecular weights of rat growth hormone and its precursor form as determined from the amino acid compositions are 2177.2 and 2462.6 respectively.

The amino acid sequence of rat GH determined solely from DNA sequences is in good agreement with the partial protein sequence for this hormone obtained by Wallis and Davies<sup>18</sup>. The

# Construction and analysis of recombinant DNA for human chorionic somatomammotropin

John Shine, Peter H. Seeburg, Joseph A. Martial, John D. Baxter & Howard M. Goodman

Department of Biochemistry and Biophysics, Metabolic Research Unit and Endocrine Research Division, School of Medicine, University of California, San Francisco, California 94143

*DNA complementary to mRNA coding for the human polypeptide hormone, chorionic somatomammotropin, has been purified by specific restriction endonuclease digestion and religation before cloning into bacterial plasmids. The primary structure of a major portion of this mRNA species is deduced from the nucleotide sequence of the recombinant DNA.*

THE polypeptide hormone human chorionic somatomammotropin (HCS, placental lactogen) is secreted by the placenta in increasing amounts during pregnancy, reaching levels of the order of 1 g per day in the last trimester<sup>1</sup>. The physiological function of this hormone is still largely unknown, but it seems to act primarily on maternal metabolism, providing important nutrients of maternal origin necessary for foetal growth<sup>2</sup>.

The primary structure of HCS is very similar to that of human growth hormone (HGH); both polypeptides contain 191 amino acids and are 85% homologous in amino acid sequence<sup>3</sup>. Such homology suggests that the genes for these two hormones, together with that coding for the related pituitary hormone prolactin, have evolved from a common ancestral gene<sup>3,4</sup>. HCS, however, is secreted solely by the placenta, whereas growth hormone production is confined to the pituitary. This set of structurally related but differentially expressed genes thus forms an excellent system for investigating the structure, evolution and regulation of closely related eukaryotic genes.

In order to determine the degree of homology in the primary structure of these genes and to investigate the feasibility of

bacterial synthesis of human polypeptide hormones, we have constructed recombinant bacterial plasmids carrying DNA transcribed from HCS mRNA. We describe here the construction of these plasmids and the determination of the nucleotide sequence of the cloned DNA. Due to the stringent requirements of working with recombinant DNA from human sources<sup>5</sup> we have developed a general approach for preparing homogeneous cDNA fragments transcribed from a complex mixture of mRNAs which should be applicable to many other mRNA species. A comparison of the primary structure determined for the coding region of HCS mRNA with that reported for rat growth hormone mRNA in the accompanying paper<sup>6</sup> demonstrates the conservation of nucleotide sequences between these two mRNA species.

## Purification of DNA complementary to HCS mRNA

Human placental RNA was isolated from a caesarian section placenta as previously described<sup>7</sup> and the poly A-containing RNA separated by chromatography on oligo dT-cellulose<sup>8</sup>. The preparation was enriched for HCS mRNA by sucrose gradient sedimentation and pooling of the fractions (11–13S) which gave rise to a predominant 550 nucleotide cDNA *Hae*III fragment (see below). The major translation product of this RNA in a wheat germ cell free system is a 24,000 molecular weight (MW) polypeptide which accounts for approximately 50% of the total synthesis (results not shown). We have previously shown this polypeptide to be a precursor form of HCS by specific antibody precipitation<sup>7</sup>, suggesting that HCS mRNA constitutes about 50% of the total mRNA in this enriched preparation. The same polyadenylated RNA was used as a template for transcription into double-

stranded cDNA (see Fig. 1 legend). This cDNA was heterodisperse as judged by polyacrylamide gel electrophoresis but gave rise to a predominant 550-base pair fragment when digested with the restriction endonuclease *Hae*III (Fig. 1, lane 1). We have previously demonstrated that this fragment is derived from DNA complementary to HCS mRNA by direct nucleotide sequencing of the corresponding single-stranded cDNA fragment<sup>7</sup>. As seen from Fig. 1, this fragment represents approximately 30% of the total cDNA synthesis, in agreement with the levels of HCS mRNA predicted from *in vitro* translation of the same RNA template.

Although unique cDNA fragments generated in this manner can be isolated from most of the other fragments by gel electrophoresis and characterised by direct sequence analysis, a significant percentage of the isolated material consists of contaminating sequences. In order to purify such cDNA fragments to near homogeneity we have developed a procedure involving specific cleavage and religation of the isolated DNA fragments and have used this approach to purify HCS cDNA as shown in Figs 1 and 2. A unique DNA fragment, generated as described above from a complex mixture of DNA fragments, is first treated with alkaline phosphatase (see below), isolated by gel electrophoresis (Fig. 1, lane 2) and then cleaved into two fragments with a second restriction endonuclease. The two major cleavage products are then re-isolated following separation by gel electrophoresis. During this step most of the contaminating sequences are removed as they will remain uncleaved or will be cleaved in a different relative position (Fig. 1, lane 3). The two isolated fragments are then religated to form the original fragment. Previous treatment of the original cDNA fragment with alkaline phosphatase ensures that these two fragments are capable of ligation to each other only in the correct orientation although self-ligation to form dimers also occurs (Fig. 1, lane 4). Isolation of the original fragment, reconstructed by ligation of its constituent digestion products, results in a DNA species which is greater than 99% homogeneous as judged by restriction endonuclease digestion and quantitation of the digestion products (Fig. 2). In order to isolate HCS cDNA for molecular cloning into bacterial plasmids, we followed the above approach using *Hha*I endonuclease to cleave the 550-base pair *Hae*III fragment as described in Figs 1 and 2.

### Molecular cloning of HCS cDNA

The purified 550-base pair *Hae*III fragment was cloned into bacterial plasmids using chemically-synthesised restriction site 'linkers'<sup>11-13</sup>. The self complementary decanucleotide (5')CCGAATTCGG(3') containing the *Eco*RI restriction endonuclease recognition and cleavage site was ligated to the HCS *Hae*III fragment (previously phosphorylated using ATP and T4 polynucleotide kinase to replace the 5' phosphates removed during purification) in a molar ratio of 50:1. Figure 3 (lane 2) shows that the *Eco*RI decamers ligated both to themselves and to the HCS cDNA. Digestion of these ligation products with *Eco*RI endonuclease results in cleavage at the *Eco*RI site of the decamers giving rise to HCS cDNA with *Eco*RI cohesive ends as well as cleaved decanucleotides (Fig. 3, lane 3). As the cleaved decamers also contain *Eco*RI termini and would compete with the cDNA for ligation to the similarly cleaved plasmid, the HCS cDNA was isolated by gel electrophoresis before ligation to the cloning vector.

The use of this decanucleotide for the cloning of the HCS cDNA fragment has the advantage that the original *Hae*III sites are recreated at each end of the DNA fragment, allowing its isolation from the plasmid in a form identical to that of the original fragment. This is particularly useful for further studies involving the use of the cloned HCS fragment as a primer for cDNA synthesis on placental mRNA or HnRNA.

For the cloning of the HCS cDNA we used the bacterial plasmid pMB9, a  $3.5 \times 10^6$  MW molecule containing a single *Eco*RI site<sup>14</sup>. Infection of *E. coli* with pMB9 confers resistance to tetracycline. To select for recombinant plasmids we developed a method for ensuring that only plasmids containing an inserted

**Fig. 1** Purification of HCS cDNA. Polyadenylated placental RNA isolated as previously described<sup>7</sup> was enriched for HCS mRNA by sedimentation in a 5–20% sucrose gradient at 4 °C in the SW 27 rotor at 25,000 r.p.m. for 16 h. The 11–13S region of the gradient was pooled and 100 µg of this RNA used for the synthesis of double-stranded cDNA as described elsewhere<sup>6</sup>. DNA synthesis was stopped by extraction with phenol-chloroform and the DNA precipitated with ethanol. Digestion of the cDNA with *Hae*III endonuclease (a gift from W. Brown) was carried out in 50 µl 6 mM Tris-HCl, pH 7.5, 6 mM MgCl<sub>2</sub>, 6 mM β-mercaptoethanol with 2 units of *Hae*III at 37 °C for 2 h, after which 0.1 units of bacterial alkaline phosphatase (Worthington, BAPF) were added and digestion continued at 60 °C for 10 min. After phenol-chloroform extraction, the DNA was precipitated with ethanol, dissolved in 20 µl 10 mM Tris-HCl, pH 8, 1 mM EDTA and electrophoresed in a 6% polyacrylamide gel. The 550-base pair fragment was excised from the gel, eluted electrophoretically and digested with 4 units of *Hha*I endonuclease (New England Biolabs) at 37 °C for 2 h in 50 µl of the same buffer used for digestion with *Hae*III endonuclease. The digestion products were then separated by electrophoresis in a 6% polyacrylamide gel and the two fragments eluted electrophoretically. The eluted fragments were combined and re-ligated in a 20 µl 66 mM Tris-HCl, pH 7.6, 9 mM MgCl<sub>2</sub>, 15 mM dithiothreitol, 1 mM ATP containing 20 µg ml<sup>-1</sup> of T<sub>4</sub> DNA ligase<sup>9</sup> at 15 °C for 2 h, diluted to 200 µl with 0.1 M NaCl, extracted with phenol-chloroform and the DNA precipitated with ethanol. The ligation products were dissolved in 20 µl 10 mM Tris-HCl, pH 8, 1 mM EDTA, separated by electrophoresis in a 6% polyacrylamide gel and the 550-base pair fragment excised and eluted electrophoretically. This fragment was used in the cloning experiments. Samples from each step in the purification procedure were analysed by electrophoresis in a 6% polyacrylamide gel in 50 mM Tris-borate, pH 8, 1 mM EDTA at 100 V for 2 h. After electrophoresis the gel was dried and exposed to X-ray film (Kodak NS2T) to visualise the labelled fragments. *a*, *Hae*III digest of total placental cDNA; *b*, the 550-base pair HCS *Hae*III fragment isolated from (*a*); *c*, *Hha*I digest of the isolated *Hae*III fragment; *d*, re-ligation of the separately isolated *Hha*I digestion products; *e*, the 550-base pair fragment regenerated by ligation of its constituent *Hha*I fragments after isolation from a 6% polyacrylamide gel; *f*, <sup>32</sup>P-labelled *Hpa*II digest of ds M13 DNA used as size markers.

20  $\mu$ l 10 mM Tris-HCl, pH 8, 1 mM EDTA and subjected to electrophoresis in a 6% polyacrylamide gel. Following electrophoresis the gel was exposed to X-ray film to visualise the labelled fragments. A: a and f,  $^{32}$ P-labelled *Hae*III digest of ds M13 DNA; b and e, purified HCS cDNA *Hae*III fragment; c, *Hha*I digest of the HCS cDNA *Hae*III fragment; d, *Hpa*II digest of the HCS cDNA *Hae*III fragment. B: Scan of the autoradiogram shown in (A). a, Purified HCS cDNA *Hae*III fragment; b, *Hha*I digest of the HCS cDNA *Hae*III fragment; c, *Hpa*II digest of the HCS cDNA *Hae*III fragment. The purified HCS cDNA *Hae*III fragment was judged to be greater than 99% homogeneous by quantitation of the distribution of radioactivity in each of the two restriction endonuclease digests. Similar results were obtained by analyses of an *Xba*I digest of the purified cDNA fragment. Numbers represent c.p.m. in each fragment and in the intervening regions of the gel.

**Fig. 3** Ligation of purified HCS cDNA to *Eco*RI decamers. Purified HCS cDNA *Hae*III fragment was phosphorylated at its 5' termini (see text) using  $T_4$  polynucleotide kinase and ATP $^{10}$ . *Eco*RI decamers (5'-CCGAATTCGG-3'; a gift from R. H. Scheller) were then ligated to the fragment in a molar ratio of approximately 50:1 in 50  $\mu$ l of 66 mM Tris-HCl, pH 7.6, 9 mM MgCl $_2$ , 15 mM dithiothreitol, 1 mM ATP and 20  $\mu$ g ml $^{-1}$   $T_4$  DNA ligase $^9$ . After ligation at 4  $^{\circ}$ C for 18 h, the reaction was stopped by extraction with phenol-chloroform. The ligation products were precipitated with ethanol, redissolved in 50  $\mu$ l 100 mM NaCl, 50 mM Tris-HCl, pH 7.6, 7 mM MgCl $_2$ , and digested with 50 units *Eco*RI endonuclease at 37  $^{\circ}$ C for 2 h. Samples were analysed on an 8% polyacrylamide gel as described in the legend to Fig. 1. a,  $^{32}$ P-labelled *Hae*III digest of ds M13 DNA; b, ligation of *Eco*RI decamers to the purified HCS *Hae*III fragment; c, *Eco*RI endonuclease digest of the ligation products shown in b.

**Fig. 2** Purity of HCS cDNA used for molecular cloning. The isolated HCS cDNA *Hae*III fragment, purified as described in Fig. 1, was digested with either *Hha*I or *Hpa*II (New England Biolabs) in 50  $\mu$ l 6 mM Tris-HCl, pH 7.6, 6 mM MgCl $_2$ , 6 mM  $\beta$ -mercaptoethanol at 37  $^{\circ}$ C for 2 h and terminally labelled using [ $\gamma$ - $^{32}$ P]ATP and  $T_4$  polynucleotide kinase $^{10}$ . The labelled digestion mix was extracted with phenol-chloroform and the DNA separated from unincorporated [ $\gamma$ - $^{32}$ P]ATP by chromatography on Sephadex G-50. The labelled fragments were precipitated with ethanol, resuspended in

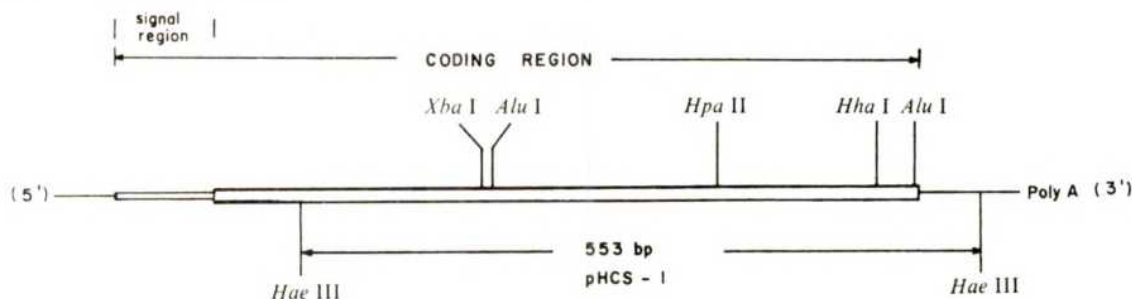

Fig. 4 Schematic representation of HCS mRNA showing restriction endonuclease cleavage sites in the corresponding cDNA. Only those restriction sites used in the present analysis are shown.

Fig. 5 Autoradiograms of 20% acrylamide-7 M urea gels used for sequence analysis of the cloned HCS cDNA fragment. The 550-base pair fragment released from pHCS-1 by *Eco*RI digestion was isolated by electrophoresis in a 6% polyacrylamide gel and the 5' termini labelled using [ $\gamma$ - $^{32}$ P]ATP and  $T_4$  polynucleotide kinase<sup>10</sup>. The labelled DNA was then incubated in 50  $\mu$ l 6 mM Tris-HCl, pH 7.6, 6 mM MgCl<sub>2</sub>, 6 mM  $\beta$ -mercaptoethanol containing 5 units of *Hpa*II at 37 °C for 2 h. The reaction was stopped by extraction with phenol-chloroform and the DNA precipitated with ethanol. The digestion products were dissolved in 50  $\mu$ l 10 mM Tris-HCl, pH 8, 1 mM EDTA, subjected to electrophoresis in an 8% polyacrylamide gel and the two labelled fragments eluted electrophoretically. Each fragment was then subjected to the four base-specific cleavage reactions described by Maxam and Gilbert<sup>15</sup> and the cleavage products analysed on a 20% acrylamide-7 M urea gel [40  $\times$  40  $\times$  0.2 cm] run at 1,000 V for 36 h. To visualise the terminally labelled fragments the gel was exposed to X-ray film (Kodak NS-54T) at -20 °C for 2 d. a, b, c, The 3'-terminal *Eco*RI-*Hpa*II fragment. Samples were loaded on the gel at 12 h intervals in the order c-b-a. d, e, The 5'-terminal *Eco*RI-*Hpa*II fragment. Sample (e) was loaded 12 h after d. G', A', T', C' refer to the respective base-specific cleavages as described by Maxam and Gilbert<sup>15</sup>. The nucleotide sequence can be read directly from the autoradiogram as shown for the 5'-terminal sequence of each fragment. \*The second C residue in the two sequences CCAGG is not seen on the gel as this is methylated in *E. coli* X1776 and hence is not cleaved during the chemical modification and cleavage reactions. Such a methylation does not affect *Hae*III cleavage at one of these sites (GGCCAGG) although it does prevent *Eco*RII cleavage at these sequences and at the CCTGG sequence found elsewhere in the cloned HCS DNA.

**Fig. 6** Nucleotide sequence of cloned HCS cDNA. The nucleotide sequence of restriction endonuclease generated fragments was determined as described in Fig. 5 legend. Only those sequences determined directly are shown in bold type. The complementary sequences are shown in italics and sequences derived from the *Eco*RI linkers are boxed. The cloned sequences were obtained by digestion of the *Eco*RI-generated fragment of pHCS-1 with either *Alu*I, *Hpa*II or *Hha*I (Fig. 4), 5'-terminal labelling of the fragments using [ $\gamma$ - $^{32}$ P]ATP and  $T_4$  polynucleotide kinase and separation of individually labelled fragments by either strand separation<sup>15</sup> (for the 5'-terminal *Alu*I fragment) or a second restriction endonuclease cleavage. The sequence is underlined where we have previously determined it directly from cDNA<sup>7</sup>. Nucleotides are numbered from the first nucleotide in the codon specifying amino acid number one (Val) in HCS<sup>3</sup>.

DNA fragment were capable of transformation. This was necessary as incorporation of DNA into the *Eco*RI site of pMB9 does not affect tetracycline resistance or any other known property of the plasmid resulting in the absence of any phenotypic difference between recombinant and normal plasmids. We therefore first treated *Eco*RI-cut pMB9 with alkaline phosphatase. This removes the 5' phosphates from the *Eco*RI-generated ends of the plasmid and prevents self-ligation of the plasmid DNA, ensuring that circle formation (and hence transformation) is dependent on the insertion of a DNA fragment containing 5' phosphorylated termini<sup>13</sup>.

The mixture containing recombinant HCS cDNA-pMB9 was used to transform the EK2 host *E. coli* X1776 as described in the accompanying article, and transformants selected by growth on medium containing tetracycline 20  $\mu$ g ml<sup>-1</sup> (work done in P3 facility in compliance with NIH guidelines). Four transformants

were obtained, all of which contained a 550-base pair insertion which was released from the plasmid DNA by either *Eco*RI or *Hae*III endonuclease digestion (see above). Furthermore, the restriction pattern of each of the four cloned DNA fragments was identical to that of the HCS cDNA fragment when cleaved with the endonucleases *Xba*I, *Hpa*II, *Alu*I and *Hha*I (see Fig. 4).

## Sequence analysis of cloned DNA

Plasmid DNA prepared from one of the clones (pHCS-1) was cleaved with *Eco*RI endonuclease and the 550-base pair insertion isolated from linear pMB9 by electrophoresis in a 6% polyacrylamide gel and subjected to DNA sequence analysis using the procedure of Maxam and Gilbert<sup>15</sup> as shown in Fig. 5. The complete nucleotide sequence of the *Eco*RI-generated fragment was determined by separate sequence analysis of the fragments

**Fig. 7** Primary structure of HCS mRNA. The nucleotide sequence of HCS mRNA was deduced from the DNA sequence determined from the cloned fragment in pHCS-1 (as shown in Fig. 6). Numbers above the sequence indicate the amino acid number from the known sequence of HCS<sup>3</sup>. The large palindrome in the 3'-untranslated region is underlined with an arrow indicating its centre of symmetry.

**Fig. 9** Conservation of nucleotide sequences in the coding region of HCS and rat growth hormone mRNAs. Two portions of the mRNA coding region of HCS (amino acids 77–96 and 128–147) and rat growth hormone (RGH) (76–95 and 126–145) are shown where the homology in amino acid sequence is high. Silent nucleotide changes (which do not result in an amino acid change) are boxed.

produced by *AluI*, *HhaI* or *HpaII* endonuclease cleavage of the DNA (Fig. 6). By comparison with the known amino acid sequence of HCS, the 557 nucleotide sequence shown in Fig. 7 represents that portion of the coding region of HCS mRNA from amino acids 24–191, plus 50 nucleotides of the 3'-untranslated region. The amino acid sequence predicted from the nucleotide sequence is identical with that previously published<sup>3</sup> confirming the validity of amino acid sequence determination by nucleotide sequence analysis.

The fidelity of cDNA cloning in bacterial plasmids is seen from the presence of identical sequences in the cloned DNA and those previously determined directly by cDNA sequencing<sup>7</sup>. This is also shown in the accompanying paper on rat growth hormone mRNA<sup>6</sup> and demonstrates the validity of using recombinant DNA for structural studies of eukaryotic genes and will allow examination of the fidelity of expression of these genes in bacteria.

## Primary structure of HCS mRNA

An analysis of the coding region of HCS mRNA indicates that codon utilisation is non-random with certain strongly preferred codon choices for some of the amino acids (Fig. 8). A very similar pattern of codon utilisation is seen in rat growth hormone mRNA<sup>6</sup> which is reflected in the conservation of sequences found between these two mRNA species (see below). Preferential codon utilisation, which is clearly different from that seen in bacteriophage and SV40 mRNAs<sup>16–18</sup>, has also been previously observed

Phe	UUU	2	Ser	UCU	2	Tyr	UAU	4	Cys	UGU	1
	UUC	8		UCC	5		UAC	4		UGC	3
Leu	UUA	–		UCA	1	Term.	UAA	–	Term.	UAG	–

**Fig. 8** Codon utilisation in HCS mRNA. Term, termination signal.

in rabbit  $\beta$ -globin mRNA<sup>19</sup> and rat insulin mRNA<sup>13</sup>. The use of certain codons (for example, CUC and CUG for Leu, GAC for Asp, AAG for Lys) seems to be favoured in all eukaryotic cellular mRNAs examined to date, while others are apparently strongly selected against (for example, UUA for Leu, AUA for Ile, GUA for Val). Such codon selection reflects the apparent preference for C or G in the third position of eukaryotic codons. In the coding region of HCS mRNA, 75 codons (46%) terminate in C, 53 (33%) in G (excluding AUG and UGG, which only have one codon), but only 17 (10%) end in U and 17 in A (10%) (Fig. 8).

Comparison of the coding regions of HCS and rat growth hormone mRNA demonstrates the conservation of nucleotide sequences between these two mRNA species with very few 'silent'

codon changes (Fig. 9), supporting the suggestion that the structural genes for chorionic somatomammotropin and growth hormone have evolved by duplication of a common ancestral gene. Such sequence conservation between related mRNAs from diverse organisms is likely to result from several factors, including selection of a favoured mRNA structure and the availability of specific isoaccepting tRNAs.

The 3'-untranslated region of HCS mRNA is characterised by a large palindromic sequence (5'-GUGACCCCUCCCC-AGUG-3') previously seen from direct sequence analysis of cDNA fragments<sup>7</sup>. In contrast to the coding region, most of the 3'-untranslated region of rat growth hormone mRNA shows very little homology with the region determined in HCS mRNA although a somewhat similar palindromic-type sequence containing oligo C tracts (5'-UCCCCCGUUAACCCCU-3') is found in a corresponding position in rat growth hormone mRNA<sup>6</sup>. Other palindromic sequences are also present in a similar position in the 3'-untranslated region of human  $\alpha$  globin mRNA (5'-UCCUCCCCUCCU-3')<sup>20</sup> and human  $\beta$ -globin mRNA (5'-GGGGGAUUAUGAAGGG-3')<sup>21</sup>. The function of such symmetrical sequences is not known, but they may represent recognition sites for specific protein-nucleic acid interactions involved in the regulation of transcription, translation or processing of the mRNA.

Amplification in bacterial plasmids of HCS gene sequences provides a probe to study regulation of this gene (and the closely related growth hormone gene) in normal and pathological states. The fidelity shown in the replication of these sequences in bacteria will also allow investigation of the expression of eukaryotic structural gene sequences when linked to bacterial promoters in a manner defined at the molecular level.

We thank Dr H. L. Heyneker for T<sub>4</sub> polynucleotide kinase and DNA ligase and F. DeNoto for excellent technical assistance. Avian myeloblastosis virus reverse transcriptase was kindly provided by the Office of Program Resources and Logistics, Viral Cancer Program, NCI. P.H.S. is the recipient of a fellowship from Deutsche Forschungsgemeinschaft. J.D.B. is an investigator of the Howard Hughes Medical Institute. ## Black holes in closed universes

BLACK holes are now the subject matter of at least half the papers in general relativity. These papers rest on a foundation of sand, for black holes have been successfully defined only in asymptotically flat spacetimes, and no one really believes that the Universe is asymptotically flat. I shall provide a firm basis for black hole physics in the present paper; I shall extend the concept of 'black hole' to arbitrary stably causal spacetimes by essentially defining a black hole to be that object which contains all the 'small' trapped surfaces. As for most astrophysical applications black hole surfaces are located approximately by the outermost trapped surface boundary, this new definition allows results which depend only on the local behaviour of black holes in asymptotically flat spacetimes to be extended (approximately) to closed universes. Results which depend on the global behaviour of black holes cannot in general be extended to closed universes. For example, it is shown that the black hole area theorem—the statement that black holes never decrease their cross-sectional area—cannot be extended to closed universes. The new concept of black hole yields a purely geometrical definition of time direction in closed universes. My notation will be that of ref. 1.

**Definition:** a black hole is the closure of the topologically smallest future set  $I^+$  such that (a)  $I^+$  contains all non-cosmological trapped surfaces; (b) the boundary of  $I^+$  is generated by null geodesic segments which are boundary generators of TIPs.

(In the topological sense, a set  $A_i$  is the smallest member of  $\{A_i\}$  if  $A_i \subseteq A_j$  for all  $i, j$ .) A black hole as defined above is a 4-dimensional object. A 3-dimensional black hole—a concept useful for discussing black hole collisions—can be obtained by intersecting the black hole defined above with a partial Cauchy surface. This is analogous to the procedure used in asymptotically flat spacetimes to obtain a 3-dimensional black hole (ref. 1, p 315).

The distinction between cosmological and non-cosmological trapped surfaces can be clarified by comparing the spherical trapped surfaces in Schwarzschild spacetime with the spherical trapped surfaces appearing in the contracting phase of a closed Friedmann universe<sup>2</sup>. In both cases the boundary of the trapped surface region  $T$  is a marginally trapped surface  $\partial T$  with  ${}_1\chi_{ab}g^{ab} = 0$  and  ${}_2\chi_{ab}g^{ab} < 0$ . (That is, one family of null geodesics orthogonal to  $\partial T$  has zero divergence at  $\partial T$ , while the other family has negative divergence at  $\partial T$ .  ${}_1\chi_{ab}$  is a null second fundamental form of  $\partial T$ .) In the Schwarzschild case the family with  ${}_1\chi_{ab}g^{ab} < 0$  points toward the trapped surfaces defining  $\partial T$ , while in the Friedmann case the  ${}_1\chi_{ab}g^{ab} < 0$  family points away from the trapped surfaces. I propose to make this distinction general.

**Definition:** for any stably casual spacetime  $(M, g)$ , let  $\partial T$  be a marginally trapped surface such that  $\partial T$  is part of the boundary of a continuous set  $T$  of acausally related trapped surfaces, and  ${}_1\chi_{ab}g^{ab} < 0$ ,  ${}_2\chi_{ab}g^{ab} = 0$ . If the family of null geodesics defined by the form  ${}_1\chi_{ab}$  point in the direction of the trapped surfaces  $T$ , then any element of  $T$  together with any trapped surface constructed by continuously deforming an element of  $T$  so that each element of the deformation is a trapped surface and is acausal with respect to all elements of  $T$ , will be called a non-cosmological trapped surface. Trapped surfaces in  $(M, g)$  which cannot be generated by the above procedure will be considered cosmological.

Recall (ref. 1, p 315) that a black hole is defined in an asymptotically flat spacetime  $(M, g)$  to be set  $M - J^-(I^+) \equiv B$ . It is known that this set contains all trapped surfaces (ref. 1,

p 311), and that its boundary is generated by the boundary generators of TIPs. It can be shown that if  $B$  arises to the future of a Cauchy surface and approaches a Kerr–Newman black hole limit, then the new definition is equivalent to the old. The details of this result will be published elsewhere.

John Wheeler is the most ardent proponent of the one-cycle closed universe<sup>3</sup>. I shall make his conception of cosmology precise by defining a Wheeler Universe to be a globally hyperbolic spacetime which is closed in space (the Cauchy surfaces are compact), and closed in time (all inextendible null geodesics are past and future incomplete and  $d(M, M)$  is finite). It is generally believed<sup>4</sup> that in the physically realistic case, an incomplete causal geodesic terminates in a singularity which destroys everything which enters it. This type of singularity I have termed<sup>5</sup> a 'strong curvature singularity'—more precisely, a point  $p$  on the b-boundary is said to be such a singularity if for every causal geodesic  $\lambda(t)$  which intersects  $p$ , all linearly independent vorticity-free Jacobi fields along  $\lambda(t)$  which are normal to the tangent vector of  $\lambda(t)$  define a volume (or area) element which vanishes as  $\lambda$  approaches  $p$ .

Thus it is expected that a physically realistic closed universe would be a Wheeler universe which begins and ends in strong curvature singularities. I will now show that black holes in physically realistic closed universes can violate the black hole area theorem.

**Theorem:** let  $(M, g)$  be a Wheeler universe for which all points on the b-boundary are strong curvature singularities. Let  $B$  be a black hole such that the null geodesic generators of  $\partial B$  all have a past endpoint at the same point  $p \in M$ . If the null convergence condition holds, then  $B$  does not satisfy the black hole area theorem.

**Proof:** there exists a Cauchy surface  $S_1$  with  $p \ll S_1$  and  $J^+(p) \cap S_1$  compact. Since all generators of  $\partial B$  intersect  $p$ , and since  $\partial B$  and  $J^+(p)$  are both closed and without boundary, we must have  $\partial B = J^+(p)$ . Hence  $\partial B \cap S_1$  is compact. The divergence  $\theta$  of the null geodesic generators of  $\partial B$  varies continuously on  $\partial B \cap S_1$ . Furthermore, since  $\partial B$  is achronal,  $\theta$  can have the value  $-\infty$  only at the point  $p$  on any generator  $\gamma$ . Now  $\theta$  satisfies the same equation as the expansion of the area defined by the vorticity-free linearly independent Jacobi fields along  $\gamma$ . Hence  $\theta$  approaches  $-\infty$  as the future limit of the affine parameter is approached, since  $\gamma$  terminates in a strong curvature singularity and the area defined by linearly independent Jacobi fields vanishes if and only if  $\theta$  approaches  $-\infty$  (ref. 1, p 100). Since the null convergence condition holds, once  $\theta$  becomes negative, it remains negative for the remainder of  $\gamma$ 's future history. Since  $(M, g)$  is globally hyperbolic,  $M = S \times R^1$ ; we can foliate  $M$  with Cauchy surfaces  $S(\tau)$ , and we can choose  $S_1 = S(\tau_1)$ . By an argument similar to that of proposition 7.24 of ref. 6, the point on  $\partial B$  at which  $\theta$  of a geodesic generator first becomes negative varies continuously with the generator  $\gamma$ . Let  $t_0$  be the affine parameter distance to the future of  $\partial B \cap S_1$  along a generator  $\gamma(t)$  at which  $\theta$  first becomes negative, with  $t_0 = 0$  if  $\theta$  is negative at  $\partial B \cap S_1$ .  $t_0$  is thus a continuous function on the compact set  $\partial B \cap S_1$ , and so it achieves its upper bound. Hence there is a Cauchy surface  $S(\tau_2)$  to the future of  $S(\tau_1)$  for which  $\theta$  is negative along every null geodesic generator of  $\partial B$  at every point in  $\partial B \cap J^+(S(\tau_2))$ . Thus the cross-sectional area of  $\partial B$  decreases, and this contradicts the black hole area theorem, which says the area never decreases.

A spherically symmetric black hole which forms by gravitational collapse in a closed Friedmann universe would satisfy the conditions of the above theorem if the matter tensor were chosen

so that the global hyperbolicity requirement and the b-boundary condition were obeyed<sup>7,8</sup>.

Many authors (for example, ref. 9) have discussed the connection between Time's Arrow and black holes. The general consensus seems to be that one obtains a preferred direction of time only in those universes for which the initial conditions allow more black holes than white holes. If this connection between entropy increase and black holes is correct, then it is possible to use the new concept of black hole to define the direction of time geometrically—no reference to the behaviour of matter is made.

**Definition:** let  $(M, g)$  be a stably causal spacetime. The future time direction of  $(M, g)$  will be the direction of time for which the volume (in the metric  $g$ ) of the region generated by all non-cosmological trapped surfaces is greatest.

This definition assumes, of course, that the volume occupied by the black holes is finite at least in one time direction. This is clearly true in Wheeler universes which begin and end in strong curvature singularities, for in this case the total volume of spacetime is finite. The relationship between the above geometrical time direction and the directions of time as defined by other, non-gravitational, physical processes will be discussed elsewhere.

## Detection of H<sub>2</sub>O emission from galaxy NGC253

THE 6<sub>16</sub>–5<sub>23</sub> transition of water vapour at 22.235 GHz was observed for the first time in an external galaxy by Churchwell *et al.*<sup>1</sup> in M33 with the 100-m Effelsberg radio telescope in late 1976, after some previous unsuccessful searches<sup>2,3</sup>. We report here the second detection of H<sub>2</sub>O emission from an external galaxy, NGC253, a large edge-on spiral galaxy situated at 3.4 Mpc (ref. 4), about five times farther away than M33. Previous observations of other molecules pointed NGC253 as a good candidate for H<sub>2</sub>O emission: OH was detected by Weliachew<sup>5</sup> and confirmed by other workers<sup>6,7</sup>; CO was detected by Rickard *et al.*<sup>8</sup> and by Solomon and Zafra<sup>9</sup>, and H<sub>2</sub>CO was detected by Gardner and Whiteoak<sup>10</sup>. The time schedule of the 13.7-m Itapetinga radio telescope during 1977 May permitted a very long integration to be performed on this object, which is observable more than seven hours a day at elevation angles greater than 30°. The observations were made with a double sideband balanced mixer receiver of about 1,000 K system temperature and a 46 channel, 100 kHz resolution filter bank. Beam switching at a frequency of about 100 Hz was used, the main beam and then the 9' reference beam being pointed at the nucleus of NGC253 for alternate intervals of 1 min. The sign of the recorded signal was changed every minute by the data acquisition computer, so that possible zero-level offsets of the channels were eliminated. One-hour integrations were made with the filter bank centred alternatively

**Fig. 1** The H<sub>2</sub>O (6<sub>16</sub>–5<sub>23</sub>) spectrum of NGC253. The error bars are equal to twice the standard error of the mean obtained for each channel. The continuum flux of the nucleus of NGC253 has already been removed from the spectrum obtained from observations.

at three different frequencies in order to obtain greater velocity coverage, until a total on-source integration time of 21 h was completed at each frequency band. The data analysis program corrected the antenna temperatures for atmospheric attenuation as a function of zenith angle  $\exp(-\tau \sec z)$  and then investigated the distribution of the results of the one-hour observations for each channel, giving the standard error of the mean and rejecting data more than  $3\sigma$  different from average values; the channels were subsequently averaged two by two, simulating a 200 kHz resolution system.

The H<sub>2</sub>O spectrum of NGC253 is presented in Fig. 1, with error bars representing twice the standard error of the mean. An emission feature of  $5.2 \pm 1.2$  Jy appears at  $v = 233$  km s<sup>-1</sup>, this is possibly associated with the same emitting region which produces the 1667 MHz OH emission observed by Gardner and Whiteoak at 239 km s<sup>-1</sup> (246 km s<sup>-1</sup> heliocentric) as such small velocity differences between OH and H<sub>2</sub>O peaks are common in the sources of our galaxy, while the total velocity range due to rotation in NGC253 is larger than 200 km s<sup>-1</sup>. We have no precise information on the position of the H<sub>2</sub>O source since the 4' beam is an important fraction of the 23' × 5' galaxy. The intrinsic power of the H<sub>2</sub>O emission at 233 km s<sup>-1</sup> is about three times greater than that of W49, the strongest H<sub>2</sub>O source of our galaxy, during its maxima. The H<sub>2</sub>O emission is, however, not so anomalous as the OH emission, as Gardner and Whiteoak estimated for the OH emission at 239 km s<sup>-1</sup> an output power about two orders of magnitude greater than that of the most powerful Class I OH sources.

We thank E. Scalise, Jr and A. M. G. Balboa for help during observations and P. Kaufmann for useful discussions.

## Detection of intergalactic gas in distant, rich clusters

WE have detected a reduction in intensity or 'cooling' of the cosmic microwave background as this radiation passes through several rich clusters of galaxies. These observations imply the presence of substantial quantities of hot intergalactic gas in the clusters observed. The 'cooling' effect, due to inverse Compton scattering of the microwave photons by hot intergalactic gas in the clusters, was predicted earlier by Sunyaev and Zel'dovich<sup>1</sup>. The fractional change in the intensity of the microwave background is given by

$$\frac{\Delta I}{I} = \frac{x e^x}{e^x - 1} \left[ \frac{x}{\tanh(x/2)} - 4 \right] \int_0^{\tau} \frac{k T_e}{m_e c^2} d\tau \quad (1)$$

where  $x$  is related to the observing frequency by  $x = h\nu/kT_r$ , with  $T_r$  the temperature of the microwave background, taken to be 2.7 K;  $\tau$  is the total optical depth for Thomson scattering through a cluster; and  $m_e$  and  $T_e$  are the electron mass and electron temperature of the hot gas. Gull and Northover<sup>2</sup>, observing at  $\lambda = 3$  cm, have recently reported evidence for this effect in several clusters. We have tried to confirm their work at somewhat higher sensitivity, and at a shorter wavelength. A shorter wavelength was chosen to lessen interference and confusion by radio sources in or near the clusters observed. Our results on eight clusters which are Uhuru X-ray sources will be reported elsewhere<sup>3</sup>. In general, we were able to set  $2\sigma$  limits of  $\lesssim 4 \times 10^{-4}$  K on the reduction in temperature of the cosmic background; in some cases these limits lie below the results reported by Gull and Northover. We do see statistically significant evidence for the 'cooling' effect in three clusters, however—all of which are in Abell<sup>4</sup> richness class 4. In the case of one of the three, Abell 2218, our results confirm the measurement of  $\Delta T = -1.94 \pm 0.54$  mK by Gull and Northover<sup>2</sup>. Here we call attention to the apparent strong correlation between the richness class and the detectability of the inverse

aperture and beam efficiency<sup>3</sup>, using a figure of 40%. We note that each of these values of  $\Delta T$  is larger in magnitude than any  $\Delta T$  measured for nearby, but less rich, clusters such as Coma or Abell 576.

Four corrections to the tabulated results are necessary before they can be used to draw inferences about the amount and distribution of ionised matter in these clusters. First, the observed  $\Delta T$  values are expressed in antenna temperature, and must be converted to differences in thermodynamic temperature for comparison with the 2.7 K background. The correction factor is 1.027. This reduction in the sensitivity of the results is more than off-set by an increase in the magnitude of the function of  $x$  in equation (1). With these two corrections applied, we find

$$\int_0^{\tau} \frac{k T_e}{m_e c^2} d\tau = -0.15 \Delta T$$

Next, the antenna pattern must be convolved with the surface brightness distribution of the source. The latter, of course, is model dependent. If we adopt, for instance, the adiabatic model of Sarazin and Bahcall<sup>5</sup>, with  $T_e = 10^8$  K,  $H_0 = 55$  km s<sup>-1</sup> per Mpc, and a cluster core radius of 0.25 Mpc, we find the values of the average proton number density given in Table 1. Fourth and finally, a correction should be made for the finite separation of our beams (9.0') compared to the cluster radii. For the Sarazin and Bahcall models, however, this correction can be neglected for these distant clusters.

The large size of the microwave effect and the inferred values of  $n_0$  suggest that these clusters should be luminous X-ray sources<sup>11</sup>. That they are not included in the 4U catalogue is no doubt due to their distance: all are Abell distance class 6. Our results do suggest, however, that these rich clusters—despite their distance—should be readily detected by the next generation of X-ray satellites, and that they may prove to be among the most luminous X-ray clusters.

**Table 1** Richness class 4 clusters observed. The measured changes in temperature, with their associated standard deviations of the mean, are given. The approximate values of the proton density in the clusters are derived under the assumptions listed in the text.

Abell cluster	$\alpha_{1950}$	$\delta_{1950}$	$(\Delta T \text{ mK})$	Inferred $n_0$ ( $10^{-3} \text{ cm}^{-3}$ )
1689	13h08m58s	-01° 06.5'	$-1.06 \pm 0.46$	$5 \pm 2$
2125	15h40m26s	+66° 28.8'	$-3.10 \pm 0.34$	$14 \pm 1.5$
2218	16h35m43s	+66° 19.5'	$-2.65 \pm 0.23$	$12 \pm 1$

Compton 'cooling'. These results may be of interest to those constructing models for the intergalactic plasma in clusters<sup>5-11</sup>, especially when the results are combined with the more sensitive X-ray observations we can expect if the new HEAO satellites are successful.

Our measurements were made at  $\lambda = 9$  mm at the Cassegrain focus of the 11-m NRAO\* telescope in Tucson, Arizona, during excellent weather in April 1977. The National Radio Astronomy Observatory is operated by Associated Universities, Inc., under contract with the NSF. At the time we used them, the dual receivers had system temperatures of  $\sim 560$  K (double sideband), with  $\Delta\nu = 10^9$  Hz. The telescope beam was 3.6' full width at half-power; we employed beam switching in azimuth with a beam throw of 9.0'.

Three richness class 4 clusters were observed for periods of 5–9 h; 'cooling' of the microwave background was detected in all of them. The observed changes in temperature and the associated standard deviations of the means are shown in Table 1. All data were weighted equally in forming these means. The values shown in Table 1 have been corrected for atmospheric extinction, and for

## Radio polarisation of quasars with optical absorption spectra

CONWAY and Gilbert<sup>1</sup> have noted that the mean linear polarisation at wavelength  $\lambda$  49 cm of highly redshifted quasars is significantly less for those with optical absorption lines compared with those with none. They suggested that the cause was Faraday depolarisation in the same regions responsible for the absorption lines. Gardner and Whiteoak<sup>2</sup> pointed out similar differences between the two quasar types at  $\lambda\lambda$  11 cm and 6 cm. They regarded lower intrinsic polarisation of absorption-line quasars as a more likely explanation. Both findings were based on extremely small statistical samples. Subsequently much more data have become available at both optical and radio wavelengths. The significance of absorption-line quasars has also been enhanced. We therefore undertook a study using today's greater set of data.

**Table 1** Linear Polarisation of quasars, all  $Z_{em}$  values

		Received wavelength (cm)				
		3.7	6	11	31	49
Absorption lines	Number	21	16	24	17	16

	Median	2.8%	3.6%	2.3%	1.7%	0.9%
	Mean	$3.03 \pm 0.39\%$	$4.29 \pm 0.57\%$	$3.01 \pm 0.29\%$	$2.01 \pm 0.29\%$	$1.35 \pm 0.33\%$
		Difference	$-1.22 \pm 1.20\%$	$-0.51 \pm 0.90\%$	$0.39 \pm 0.48\%$	$0.40 \pm 0.43\%$

Measurements of linear polarisation at various radio wavelengths were taken from refs 3–10. Where several measurements existed for a given source at one wavelength, an average value was used. To be considered a quasar, a source had to be in the catalogue of Burbidge *et al.*<sup>11</sup>, which also served as a reference for redshifts.

We calculated the mean and the median linear polarisation for various types of quasars at wavelengths  $\lambda\lambda$  3.7, 6, 11, 31, and 49 cm. Results are summarised in Tables 1 and 2. Table 1 includes all quasars regardless of redshift; Table 2 only those with  $z_{em} > 1.25$ , the redshift criterion of the earlier studies<sup>1,2</sup>. The basic division is between those quasars having, and those not having, absorption lines. In Table 1 only, the latter are subdivided into three groups: (1) all quasars with non-absorption spectra; (2) the first 26 of them, in order of right ascension, constituting a sample comparable in size to that for the absorption-line quasars; and (3) a set consisting of quasars selected by emission redshift to match the emission redshift of an absorption-line mate. (The absorption-line quasars OQ172 and OH471, both with  $Z_{em} > 3$ , could not be matched better than  $|\Delta Z_{em}| \sim 0.8$ .)

In no case do we find a difference in mean linear polarisation between absorption and non-absorption quasars as large as two standard deviations. Only at  $\lambda$  3.7 cm do we find differences in means even slightly larger than their associated errors, and these usually in the sense that absorption-line quasars have higher mean polarisations. We conclude that the linear polarisation properties of quasars having absorption lines are indistinguishable from those not having absorption lines.

This work was supported by the US NSF (grant MPS73-04677). We thank Joe Spector for assistance in collecting the data.

## Saturn-like ring system around Uranus

OBSERVATIONS made at Kavalur<sup>1,2</sup> of the occultation of SAO158687 by Uranus on 10 March 1977 showed, in addition to the occultation by a satellite system termed the  $\epsilon$  ring, a dimming of the light of the star close to the time when the atmosphere of the planet could have caused the phenomenon. Since then, the identities of the  $\alpha$ ,  $\beta$ ,  $\gamma$ ,  $\delta$  rings have also become well established, and a theoretical interpretation of their origin<sup>3</sup> has been proposed. We have closely examined the Kavalur photoelectric record and describe here several new features of the satellite ring system of Uranus.

Our analysis consisted of scaling the photoelectric record at close intervals to study the variation in intensity. The experimental details have been described elsewhere. After careful examination we have also picked out many large spikes not reported previously which show the nature of distribution of the occulting material in the vicinity of the planet. The scaling interval is 3 s, an order of magnitude greater than the time resolution of the recording system. After correcting for atmospheric extinction and a small linear drift in the recording system, the scaled values were grouped together to give a moving average over a time interval of 15 s. Figure 1 shows these values over the entire recording period, a striking feature is the significant reduction of light of the star during the intervals 2014 to 2031, 2032 to 2041, 2042 to 2055 and 2057 to 2106 UT. We term these zones A, B, C and D respectively. An additional zone of light loss occurs during 2108 to 2120 UT.

We interpret these zones A, B, C, D as caused by occulting material distributed in an extended region around the planet.

**Fig. 1** Observed light variations at Kavalur of SAO158687 during 2000–2130 UT 10 March 1977. At the top the locations in the time coordinate where the  $\epsilon$ ,  $\delta$ ,  $\gamma$ ,  $\beta$  and  $\alpha$  rings intercept are indicated. A second row of indices numbered 1 to 19 are new spikes of short duration that we have identified on our record. The open and filled circles associated with these represent the degree of certainty in the identification of these spikes; the filled circles denote spike amplitudes that have a confidence level greater than 99.5%, while the open circles indicate visible spikes that are less certain.

Sharp discontinuities segregate these zones. A model for such a distribution of material is shown in Fig. 2 with extended ring systems A, B, C, D, similar to the ring system one sees in Saturn. Besides the occultation path, the  $\alpha$ ,  $\beta$ ,  $\gamma$ ,  $\delta$ ,  $\epsilon$  ring condensations, the gaps in the particle distribution in the rings that appear as discontinuities, and the spike locations defining the new ring condensations that are listed in Table 1 are also marked. The distances are tentative and are on the measured basis of almanac positions of Uranus together with corrections for the relative positions of Uranus and SAO158687 according to Franz, Wasser-

man and Seidelmann<sup>4</sup>. There is also the possibility of an inclination of the plane of the ring system to that of the equatorial plane of Uranus.

The C and D rings cause the light diminution reported earlier<sup>1,2</sup>. The D-ring effects are maximum at 2102 UT. This ring is separated from the C ring by a wide gap of  $\sim 2,000$  km. The two occasions when the light of the star encounters this gap are 2056 and 2107 UT. On the first intercept there is a near-restoration in brightness. The second event at 2107 UT is less striking. The lower boundary of the D ring is unspecified; Fig. 2 shows that it could extend nearer the planetary limb. There is considerable fine structure in both the C and D rings, as over the entire light curve of Fig. 1, portraying the light variations of the entire ring system.

Rings B and A are further away from the planet. The starlight encountered the opacity of the B ring material between 2032 and 2041 in the pre-occultation phase and again after 2122 UT. The B ring is well defined in Fig. 1, by a light loss of almost five hundredths of a magnitude. Our observations end when the light of the star is still affected by this ring on the post-occultation side. But the trend towards a reduction in intensity of starlight is clear from the light curve and substantiates our interpretation. We also note the discontinuity at 2041 and 2122 UT as caused by the gap between the B and the C rings. The light of SAO158687 shone through the A ring earlier than 2031 UT. The A–B gap is short at this epoch. The outer boundary of the A ring is poorly defined, partly because of lack of continuous record and partly because of the low altitude of Uranus at that time. Ring A contains the ring-condensations  $\alpha$ ,  $\beta$ ,  $\gamma$ ,  $\delta$  and  $\epsilon$ . There is obscuring material even beyond the boundary we have assigned to ring A as evidenced by the spike labelled 1 in Table 1.

The ring-condensations shown by the spikes on the record are distributed over the three outer rings A, B, C. We present in Table 1 the observed times of 19 such events together with their confidence levels. In the neighbourhood of each spike over an 80-s

**Fig. 2** Diagrammatic representation of the Saturn-like ring system around Uranus. Dotted line indicates the lower boundary of the D ring.

interval of the record, we have evaluated the amplitudes of both positive and negative spikes that constitute the random noise. Assuming that this is gaussian we calculate the spike amplitude in terms of the standard deviation and read off from tables the confidence level for the spikes being of non-atmospheric origin. In Figs 1 and 2 we have listed only those spikes that are easily seen on the tracing; the lowest level of confidence of those in Table 1 is 97.9%.

These ring-condensations seem to vary in opacity along the ring plane. As examples, we cite the spike numbers 5 and 6 which coincide with events 4 and 5 reported by Millis, Wasserman and Birch<sup>5</sup>. Both of these events have very high confidence levels of 99.67 and 99.99% respectively on the Lowell records. (We determined this value from samples of Lowell tracing provided by Wasserman.) On the other hand, these events, on our records,

**Table 1** Confidence levels for spike events

Event no.	Confidence level (%)	Event no.	Confidence level (%)
1	99.8	11	99.8
2	99.8	12	99.8
3	99.6	13	99.5
4	99.9	14	99.0
5	98.8	15	99.0
6	99.6	16	98.9
7	99.0	17	97.9
8	99.5	18	98.1
9	99.5	19	99.2
10	99.9		

have confidence levels of 98.8 and 99.6% respectively. In fact we record spikes of higher probability of occurrence than event 5 of Millis *et al.* The inference is, therefore, that longitudinal variations of opacity in the plane of the ring-condensations exist.

An exception seems to be the relatively wide ring-condensation termed  $\epsilon$ . In Fig. 3 we give a light curve of occultation by this ring

**Fig. 3** Intensity variations caused by the  $\epsilon$  ring.

from closely spaced measures of the photoelectric tracing every quarter of a second. Note that there is much fine structure in the variation of transparency that may be due to resonances associated with Titania and Oberon as postulated by Dermott and Gold<sup>3</sup>. Also of note is the close agreement between the light curve of the ring found by Millis *et al.*<sup>5</sup> and by us, even though the intercepts with the ring are made at locations several thousand kilometres apart.

Table 2 summarises the above discussion of an extended ring system about Uranus, similar to that of Saturn. By dividing the Table into the pre- and post-occultation phases and locating events by time, we avoid the uncertainties of values of distance. If most of these particles are small and abundant enough to have

## Why is a minor planet minor?

ALL planets and satellites are generally believed to have formed by accretion of small bodies. The craters on the Moon, Mercury and Mars give clear evidence that the accretion of small bodies was of major importance, at least during the last phase of their formation. It is very likely that collision and fragmentation of planetesimals played a key part in the accretionary stage of planets. As suggested by Hartung<sup>1</sup>, accumulation and fragmentation of planetesimals may have competed in the planetary accretion process, and a planetesimal which could survive catastrophic destruction may have become a planet. On the basis of the accretion model of planet formation, we propose a new idea in which we explain why minor planets are 'minor' and could not grow to a full-size planet. These results also substantiate Orowan's<sup>2</sup> idea that terrestrial planets accreted inhomogeneously, with iron being the first to accumulate and silicates the second.

Modes of fragmentation and accumulation of planetesimals during a collision depend on material property, impact velocity, and relative size of the impacting planetesimals. To simplify the discussion we consider only a mass ratio of projectile:target of  $10^{-2}$ . If the target is the largest planetesimal in the system and the size distribution of the planetesimals follow  $dn \propto m^{-5/3} dm$ , then the planetesimals larger than the projectile of the above mass ratio comprise about 50% of the total mass. Our numerical simulation of planetary accretion<sup>3</sup> also indicates that the collision of the planetesimals with above projectile:target mass ratio may control the evolution of the total planetesimals.

As a result of collision between two planetesimals, there are three possible fates: (1) bouncing, (2) accumulation, and (3) fragmentation or net mass loss of the target planetesimal. If the collision of two planetesimals is elastic, the two planetesimals will rebound from each other and the two will not coagulate, when the impact velocity is larger than the escape velocity of the target planetesimals. If the collision is made at a very large velocity, then the two planetesimals are broken into smaller fragments and major parts of the fragments may acquire kinetic energy large enough to escape from the two-body system. If the impact velocity is between the first (elastic) case and the second (fragmentation) case, ejecta material at the impact does not have a velocity large enough to escape from the target and it may eventually accumulate on the target planetesimals. Only this case will contribute to the net growth of the planetesimal.

The critical impact velocity subdividing the above three cases depends on the material properties of the target and projectiles. For instance, if colliding bodies are very plastic, they are not easily disrupted but coagulate even at a rather high impact velocity. Orowan<sup>2</sup> first pointed out the important effect of the plastic (or ductile) property of iron on the planetary accretion process. He suggested that iron and

nickel are nucleating agents of the inner planets, because metallic particles are expected to stick together by 'cold welding' or 'hot welding' more easily than silicates.

It is important to note here that mechanical properties also change significantly with temperature. Iron is no longer ductile at temperatures below  $\sim 200$  K, as shown by an impact experiment with the Gibeon iron meteorite<sup>4</sup>. Many other metallurgical studies<sup>5</sup> also show that most irons undergo brittle-ductile transition at temperatures between 200 and 250 K. Therefore iron particles cannot be the nucleating agents at temperatures below 200–250 K. We propose here that this important factor determines the asteroid's evolution. Silicates become ductile only at a high temperature, however (for example, most silicate rocks would probably show the brittle-ductile transition at  $T \sim 1,500$  K at impact conditions of interest).

The critical velocity,  $V_{a-f}$ , subdividing the accumulation regime and fragmentation regime, is estimated as follows. According to Gault and Wedekind<sup>6</sup> and Fujiwara *et al.*<sup>7</sup> a kinetic energy of  $10^7$  erg  $g^{-1}$  will be enough to completely fragment a basaltic body. When the mass ratio of the projectile:target is  $10^{-2}$ , the velocity corresponding to the above energy is about  $0.3$  km  $s^{-1}$ ;  $V_{a-f}$  (silicate)  $\sim 0.3$  km  $s^{-1}$ . In the case of an iron target at brittle condition,  $V_{a-f}$  is 5 to 10 times larger than that for a silicate rock, because iron has a higher tensile strength and a higher failure (strain) limit; both of these being a factor of 2 or 3 higher than ordinary silicate rocks. Therefore the critical velocity,  $V_{a-f}$  (iron) may be around  $1$  km  $s^{-1}$  at a brittle (low temperature) condition. On the other hand, at a ductile condition,  $T > 200$  K for irons,  $T > 1,500$  K for silicate rocks,

**Fig. 1** Temperature and impact velocity conditions for bouncing, accumulation and fragmentation of planetesimals. The solid lines indicate boundaries for silicate material. The broken lines indicate boundaries for iron planetesimals. The symbols are for Mercury, Venus, Earth, Mars and Minor planets and show the estimated temperatures and mean impact velocities of planetesimals in each proto-planetary particulate ring. The scale of size corresponding to the escape velocity ( $=$  the mean impact velocity here) is shown. *a*, Stone rebound; *b*, stone accrete; *c*, stone disrupt; *d*, metal rebound; *e*, metal accrete; *f*, metal disrupt.

these materials are tougher than at a brittle condition, because most of the impact energy is absorbed for the plastic deformation of the material. Correspondingly, the critical velocity  $V_{a-f}$  at a ductile condition may become substantially higher than the above estimates. We expect, therefore, the boundaries dividing the accumulation and fragmentation regimes to be like those shown in Fig. 1.

The critical velocity,  $V_{b-a}$ , subdividing the bouncing and accumulation regimes is the minimum impact velocity which generates a stress higher than the elastic (tensile) limit,  $\sigma_e$ , of the material. A simple calculation yields the following values: assuming  $\sigma_e$  (silicate) = 0.5 kb, and  $\sigma_e$  (iron) = 5 kb,  $V_{b-a}$  (silicate)  $\sim 0.05 \text{ km s}^{-1}$ , and  $V_{b-a}$  (iron)  $\sim 0.2 \text{ km s}^{-1}$ . These estimates are consistent with impact experiments by Hartmann<sup>8</sup> for silicate rocks. The critical velocity  $V_{b-a}$  also changes with temperature, because the strength of the material changes with the temperature. The velocity is expected to become smaller as the temperature increases.

Thus we obtain a map of the bouncing accumulation, and fragmentation regimes as a function of temperature and impact velocity, shown in Fig. 1. We stress that Fig. 1 is only schematic, because the exact position of the boundaries might be affected by the shape, impact angles and other properties of the colliding planetesimals.

In Fig. 1, silicate planetesimals can grow only in the region *b*, and iron planetesimals in region *e*. Therefore, only the area superposed by both the regions *b* and *e* satisfies the condition for both iron and silicate planetesimals to grow. In other regions only one component of them (either iron or silicate) or neither of them, can grow.

The next problem is to estimate temperatures and mean impact velocities for planetesimals in a proto-planetary particulate disk. According to Lewis<sup>9</sup>, the bulk compositions of Mercury, Venus, Earth, Mars and the asteroids Ceres and Vesta are dominated by materials formed in the condensation temperatures around 1,400 K, 900 K, 600 K, 450 K and 250 K respectively. These temperatures may give upper bounds of planetesimal temperatures in each planet zone. Lower bounds on the planetesimal temperatures are probably given by the radiative-equilibrium temperature at the present planet positions. These are 480 K, 350 K, 300 K, 240 K and 180 K, for Mercury, Venus, Mars and the asteroids respectively. We tentatively assume that the temperature of planetesimals during the accretion-collision stage lies between these two limits.

It is also very difficult to estimate the impact velocities. If there are no dense gases in the terrestrial planet's region at the time of accretion, the planetesimal may acquire a relatively high velocity due to the distant and/or close encounters of other planetesimals. The mean relative velocity of planetesimals may be approximated by  $V^2 = (e^2 + i^2) v_k^2$ , where  $e$ ,  $i$ , and  $v_k$  are eccentricity, inclination and Kepler orbital velocity of each planet. If we take the mean eccentricity and inclination of the terrestrial planets ( $e = 0.08$  and  $i = 0.0$ ), the mean velocity of planetesimals in the terrestrial planet region becomes higher than  $1 \text{ km s}^{-1}$ .

The temperatures and the mean impact velocities estimated above are plotted in Fig. 1. As seen, almost all the data points lie in the region (*c+e*), where only iron-like materials can coagulate. This observation supports Orowan's idea that iron-like material is the nucleating agent in the terrestrial planets. Silicates could probably not accumulate until the iron-nucleus grew to about 1,000 km in radius. This result gives another dynamical mechanism for heterogeneous accretion of planets.

Figure 1 indicates that asteroids are in a marginal position; the asteroid condition may fall in region *f*. This indicates that iron-like planetesimals in the asteroid zone had difficulty in growing due to their brittleness at low temperature, so that iron could not be a nucleating agent in the asteroid zone. Probably the iron-like material could

not grow at all or would grow too slowly to become large enough to form a planetary nucleus. The small iron planetesimal also fails to capture enough silicate material for a full-size planet. Thus, it is very likely that the low temperature condition of the asteroids hampered their growth into iron-like planetesimals, which in turn inhibited the accumulation of silicate planetesimals. In conclusion, we propose that the brittleness of iron at temperatures below 200–250 K is the primary reason why minor planets are minor, and why minor planets could not grow to full-size planets.

## Kimberlites and plate-tectonics in West Africa

MESOZOIC kimberlites in West Africa are the source of most of the alluvial deposits of diamond which bolster the economies of Sierra Leone, Guinea, Liberia, Ivory Coast and Ghana. Difficulties encountered in the interpretation of geophysical, geochemical and mineralogical prospecting methods led to a structural investigation into the distribution and tectonic controls of kimberlite magmatism in eastern Sierra Leone. Here we attempt to show a correlation between the continental continuations of transform fault fracture zones and kimberlite magmatism in West Africa.

Areas of richly diamondiferous alluvial deposits, unabraded picro-ilmenite and pyrope occurrences and outcrops of kimberlite pipes and dykes indicate a broad east–north-east swathe of kimberlitic activity cutting through West Africa from Sierra Leone to northern Ghana<sup>1–4</sup>. Figure 1 shows that Mesozoic kimberlite fields within this zone of activity are frequently centred near well developed north–south brittle structures, as in eastern Sierra Leone and western Ivory Coast. In Sierra Leone, east–north-east trending kimberlite dykes cut across Archaean north–south and south-east trending structures, but parallel local east–north-east fractures confined between major north–south regional faults. Only in the coastal strip of Sierra Leone and Liberia are regional scale east–north-east structures apparent; elsewhere, they are short, disconnected structures of only local importance.

The Atlantic Ocean floor is cut by still active transform fault fracture zones which are orientated along east–north-east directions where they intersect with the coastline<sup>5,6</sup>. Two such fracture zones intersect the Sierra Leone coastline; the Guinée Fracture Zone and the Sierra Leone Fracture Zone. When traced inland their hypothetical continuations are the loci of kimberlitic intrusions, but are not major structures as in Nigeria<sup>7</sup>, being subtly incorporated into the regional structure. The Sierra Leone Frac-

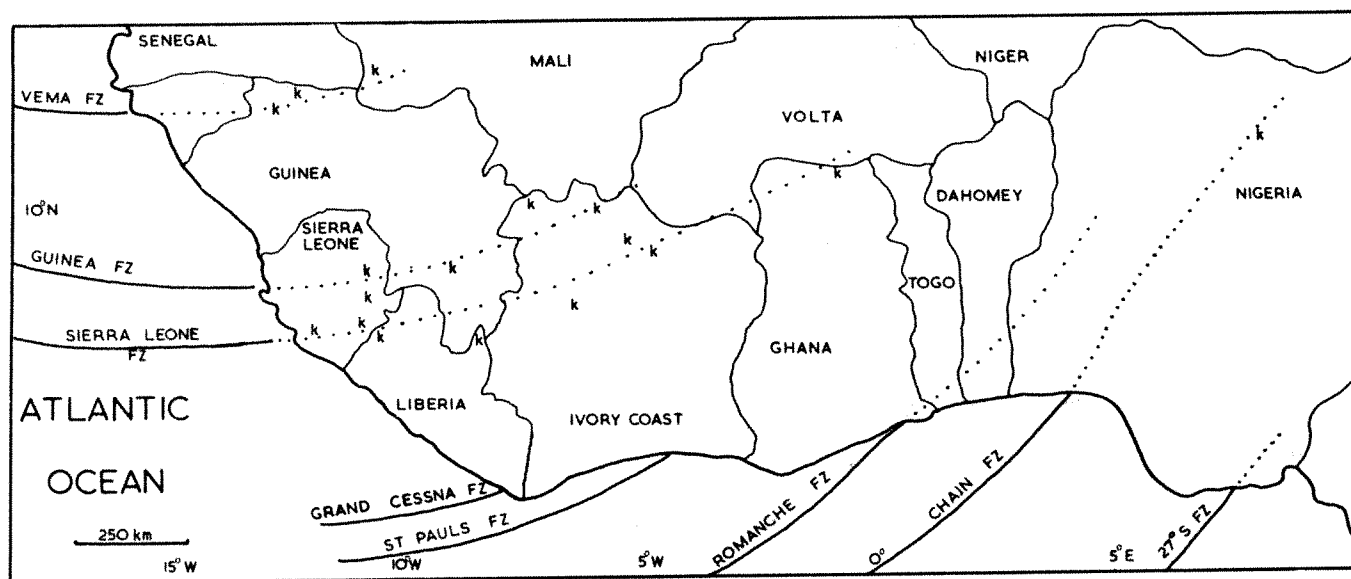

Fig. 1 West Africa, showing locations of kimberlites of probable Mesozoic age, (k); oceanic fracture zones (FZ) and their hypothetical continental continuations.

ture Zone may be traced 150 km inland as the fault-controlled estuary and course of the Sewa River, while the Guinea Fracture Zone meets the coastline at Freetown, and is recognisable as a major fault-controlled estuary along which two layered basic intrusions are developed<sup>8</sup>.

Mesozoic kimberlitic activity occurs elsewhere in West Africa, in northern Guinea and in Nigeria<sup>7</sup>. In Nigeria, kimberlite is found, as in Sierra Leone, close to the continental continuation of a major fracture zone, the Chain. In Mali<sup>4</sup>, the close association of kimberlites and Mesozoic basalts suggests a Mesozoic age for the former. In northern Guinea and Mali, the kimberlites lie on the hypothetical continental continuation of the Vema Fracture Zone. Similar relationships between magmatism and oceanic fracture zones were proposed by Marsh<sup>9</sup>. He supported the hypothesis that the continental expressions of the fracture zones were small circles about the pole of rotation of seafloor spreading. In West Africa, the pre-80 Myr spreading took place about a pole situated at 21.5°N, 14°W (ref. 10). At the time kimberlites were being intruded into the crust, the pole of rotation for the Africa-America spreading system was moving north towards its present position<sup>11</sup>. During pole migration the fracture zones and their continental expressions became activated, perhaps allowing increased penetration of kimberlitic magma into the crust. The absence of kimberlites along hypothetical continental extensions of fracture zones such as the St Pauls and Romanche may be due simply to the lack of kimberlitic magma along these structures, or to insufficient tectonism to allow its upward movement.

A relationship between kimberlites and structures associated with plate-tectonics is suggested in West Africa, and confirms a hypothesis based on south-west African data<sup>9</sup>.

## Laminar-turbulent transition in polymer solutions

WHETHER transition from laminar to turbulent flow is delayed in dilute drag-reducing polymer solutions, unchanged, or occurs at an earlier Reynold's number has been a vexing question since research began in this area. Using the classic Reynold's dye-streak technique, Giles and Pettit<sup>1</sup> showed that pipe-flow turbulence was delayed by a factor of 2 or more by small additions of polymer. Similarly, Castro and Squire<sup>2</sup> and White and McEligot<sup>3</sup> found transition delay in small pipes from measurements of pressure fluctuations and actual drag-reduction performance. But more refined pipe-flow studies by Little *et al.*<sup>4</sup> show convincing evidence for polymer solution transition earlier than for the pure solvent and this has been confirmed by laser-Doppler anemometry<sup>5</sup>. Here we show that polymer solutions in a boundary-layer flow exhibit a transition to turbulence at a lower Reynold's number than the pure water solvent.

Following the work of Brennen<sup>6</sup>, an ogival-shaped head with an axial length of 3½ inches and a base diameter of 2.34 inches was tested in the Naval Academy free-surface water tunnel. The head shape corresponds to a source distribution, cut off sharply and supported by a long sting through which air was supplied to ventilate the cavity, and through which the cavity pressure could also be measured. By ventilation, a fully developed cavity could be supported at a Reynold's number (based on ogive length) of  $3 \times 10^5$  and a cavitation number,  $\sigma$ , of 0.5 where  $\sigma = (P_T - P_c) / \frac{1}{2} \rho U^2$  and  $P_T$  and  $P_c$  are the tunnel and cavity pressures and  $U$  is the tunnel velocity (10 ft s<sup>-1</sup>). The ventilated cavity as seen by the eye is shown in Fig. 1a; the cavity rising with respect to the water flow due to its buoyancy.

When the cavity is illuminated by a stroboscope, or photographed using a short-duration flash, the series of waves shown in Fig. 1b is readily discernible on the cavity in pure-water flow. These waves represent the cavity-flow

equivalent to the instabilities in a free shear layer in a (one-phase) wake flow and have been studied by Brennen<sup>6</sup>. Note that the flow leaving the ogive surface is laminar, and the waves are part of the laminar-turbulent transition process on the surface of the cavity.

At the same tunnel velocity and pressures, but with 25 p.p.m. solution of polyacrylamide (Calgon TRO-375) instead of water, the laminar zone in the flow leaving the ogive has disappeared as shown in Fig. 1c. A similar appearance to Fig. 1c was obtained by roughening the surface of the ogive in pure water flow (although we were careful to avoid roughening the ogive surface when using polymer solution). Thus, we conclude that the presence of polymer additives causes an earlier transition to turbulence in the boundary layer of the ogive than does the pure-water flow. A similar conclusion could be drawn from photographs of water and polymer solution jets discharging in air<sup>7</sup>, but the test geometry is not as well defined as in the present study.

At the wall shear rate involved ( $10^4 \text{ s}^{-1}$ ), the presence of the polymer has increased the water viscosity in the tunnel by about 40% (as estimated from rheograms for a polymer of similar drag-reduction effectiveness<sup>8</sup>) and thus the Reynolds number for the polymer flow has decreased to around  $2 \times 10^5$ . The effect of the polymer on transition is, hence, even more marked than indicated by the photographs.

**Fig. 1** Photographs of ogive head-form in water tunnel. (Flow is from right to left.) *a*, Overall view of body and cavity; *b*, short-duration flash ( $10 \mu\text{s}$ ) showing laminar flow leaving ogive and transition to turbulence.  $Re = 3 \times 10^5$ ,  $\sigma = 0.5$ ; *c*, same tunnel velocity and pressures as *b* but 25 p.p.m. polyacrylamide solution instead of pure water.  $Re = 2 \times 10^5$ ,  $\sigma = 0.5$ .

The demonstration in polymer solution flow of a destabilising effect on transition, together with the known diminishing of turbulence production at higher Reynolds numbers should have an important influence on the development of theoretical explanations of the mechanism of polymer drag reduction.

## Time sharing and body partitioning in bat-plant pollination systems

IN the dry months from January to March in Central America there is an abundance of flowering trees and shrubs<sup>1-3</sup> and many of them are pollinated by bats. When collecting nectar, the bats visit various species of plants<sup>4-6</sup>, and in periods of peak abundance of flowers they make increasingly frequent visits. With flowering apparently synchronised<sup>3,4</sup>, there seems to be a good chance that flowers may not always receive conspecific pollen, thus reducing their seed set and fitness. The study reported here suggests that this chance is minimised because nectar and pollen are available at different times on different flower species, and because some species deposit and receive pollen at distinct regions of the bats' bodies.

Interspecific competition among plants sharing common elements of the pollinator fauna is seen in entomophilous systems when weeds or native plants prove superior to crop plants<sup>7,8</sup>. The disadvantage of being a minority species in such a community free-for-all has been shown by Levin and Anderson<sup>9</sup>—given a finite number of visits by pollinators, sharing of pollinators by plant species might decrease the chances of appropriate pollination for less numerous species, resulting in lowered seed set and eventual elimination from the community. Thus, a hypothetical case can be made for mixed species associations becoming increasingly oligotypic. But real tropical communities persist in polytypy, which shows that plants avoid this dilemma.

Sympatric insect-pollinated plants with similar phenologies seldom interbreed because they: (1) are incompatible; (2) 'use' relatively specific pollinators; (3) deposit pollen on different parts of the pollinator's body, and (4) present pollen and/or nectar rewards at different times<sup>10,11</sup>. I suggest that time sharing and body partitioning are 'escapes' from competition available to some bat-adapted plants.

The feeding habits of bats have been investigated previously by stomach and faecal analysis<sup>5,6,12</sup>, and by swabbing the fur with an adhesive substance and then examining the swabbed material microscopically<sup>4,13</sup>. Workers using such pooled pollen analyses have interpreted mixed pollen loads to indicate lack of discrimination by the bats. For example, Heithaus *et al.*<sup>4</sup> found six species of pollen in 42% of 527 loads examined and concluded that: "The high proportion of mixed pollen loads ... suggests low flower constancy in bats". But the methods used in all these studies did not or could not take into account the distribution of pollen temporally or topographically. For plants to have the benefits of pollinator specificity, bats need not feed only on one species. Effectiveness of pollination would be enhanced if bats confined each of their several nightly visits for feeding to a single species, or if they visited different species on different nights or at different times.

While working in Costa Rica and British Honduras in March 1974, 1975 and 1976, I netted bats in several sites between 1930

**Table 1** Pollen grains from fur of *Glossophaga soricina*, March 1974 and 1975

Central farm, British Honduras <i>N</i> = 26

0400-0600		200	2	1			
Santa Rosa, Costa Rica <i>N</i> = 22							
1900-2100			500			220	
2000-0200							913
0200-0400	870	20	3				640
0400-0800	300	121	17				2

and 0530 h. I swabbed pollen from the heads, shoulders, venters and rumps of glossophagine bats, making separate slide preparations for each anatomical region and noting the times of capture. Table 1 shows that *Glossophaga soricina* Pallas concentrates on *Inga* (Mimosaceae) early in the evening and switches to *Bauhinia* (Caesalpinaceae) towards dawn.

The way in which plants may reinforce or entrain such behaviour is shown in Fig. 1; nightly nectar flow is timed correspondingly. *Inga* anthers are ripe between 2000 and 2100 h, whereas *Bauhinia* anthers do not dehisce until the early morning (0400-0600 h). This suggests that the availability of pollen is also co-adapted with bat schedules. The visual acuity of nectar bats is fairly good<sup>14</sup>, and the well developed olfactory lobes and vomeronasal organ<sup>15-17</sup> indicate that olfaction plays a large role in their orientation. Flower discrimination and concomitant time-entrainment should be no more difficult for bats than for bees. As Darwin pointed out<sup>18</sup>, such constancy affords the pollinator more efficient foraging as well as facilitating appropriate pollination. Further bat and plant studies in other months or in different sites may reveal more of this trend to time partitioning.

While netting along a transect from Monte Verde, Guanacaste, Costa Rica to a point 5 km west, I captured eight female and four male *Anoura geoffroyi* Grey. Two yielded pure *Mucuna* (Papilionaceae) pollen, probably *M. urens*, placed ventrally. The other 10 carried mixed loads, *Mucuna* on the venter, *Crescentia* (Bignoniaceae) on the shoulders and mid-dorsum and pure *Inga* (six bats) or mixed *Inga* and unidentified Bombacaceae (four bats) on the face and neck. Essentially the plants were using three different and fairly constant pollinators.

These data do not preclude overlap in pollinator 'use' by many plants. For example, Alvarez and Gonzalez Quintero<sup>5</sup> found mixed pollen loads on *Glossophaga* and *Anoura*; four or five genera were often well represented. Although the methods used (stomach and faecal analysis) may have hidden a microtemporal

structure which could be revealed by further work, it is unlikely that all genera found in pooled pollen samples were involved in time sharing.

Another example is provided by *Bauhinia unguolata*, *Bombacopsis quinata*, *Ceiba pentandra*, *Luchea speciosa* and *Pseudobombax septenatum*, which can bloom synchronously in the same site<sup>19</sup>. All these bat-adapted species have morphological adaptations to deposit pollen on the head, suggesting that floral homologues 'use' identical pollinators. As Baker<sup>20</sup> indicated, taxonomically unrelated flowers may well be able to share a pollinator where the supply of that animal is adequate. Only when pollinators are scarce would such behaviour on the part of the plants become disadvantageous. At such times sympatric species which partition pollinators may be able to co-exist more successfully than those that do not<sup>21</sup>. Competition resulting from a low density of pollinators would then reinforce floral differences or promote such differentiation, reinforcing and maintaining community polytypy.

This work was supported by a grant from the National Geographic Society.

## Possible case of aggressive mimicry in a neotropical scale-eating fish

*Probolodus heterostomus*, one of the scale-eating characid fishes, is found in the coastal rivers of southeastern Brazil from Espírito Santo to São Paulo<sup>1-3</sup>. The species is usually placed in the subfamily Cheirodontinae<sup>2-4</sup> although a taxonomic affinity with the Tetragonopterinae has been suggested<sup>1</sup>. The latter view was apparently based largely on the morphological similarity of *Probolodus* with some species of *Astyanax* and especially *A. fasciatus*, a member of the

Fig. 1 *P. heterostomus* (upper) and *A. fasciatus* (lower) from the Rio Paraibuna, São Paulo. The colour of both fishes is also very similar; actual size of *Probolodus* 76 mm.

Tetragonopterinae. The external similarity between the two species, which are sympatric over the Rio Paraíba drainage, is indeed striking (Fig. 1). But data accumulated from population samples, stomach contents and the behaviour of individuals maintained in aquaria suggest that *Astyanax* is the principal prey of *Probolodus*, at least in certain areas of its range. I suggest here that the similarity between these two genera is a form of aggressive mimicry<sup>3,6</sup> irrespective of taxonomic affinities.

Thirty-five individuals of *P. heterostomus* (54–104 mm) were caught in the Rio Paraibuna, São Paulo (22°23'S, 45°40'W), on five occasions between May and July 1977. The fish were collected by means of casting net, bow-net and hook. On the same occasions a general collection of other fishes was also made. On all occasions *Probolodus* was caught together with *A. fasciatus* (total 35 individuals compared with 409) which strongly suggests that these two species shoal together or at least live in close proximity. On three occasions, 24 individuals of the curimatid *Curimatus gilberti* were also caught together with *Probolodus* and *Astyanax*. Other scale-bearing fishes found sympatrically with *Probolodus* were the erythrinid *Hoplias* (one species); the characids *Astyanax* (two additional species), *Hyphessobrycon* (one species) and *Oligosarcus* (one species); the anostomid *Leporinus* (two species), and the cichlids *Geophagus* (one species), *Cichla* (one species) and the introduced *Tilapia* (one species). For these, no comparable numerical data were obtained but they were far less numerous than *A. fasciatus* and only incidentally collected together with it and *Probolodus*.

With the exception of four individuals which were maintained alive all *Probolodus* were killed immediately and preserved. These preserved specimens were scored for length and their stomach contents were analysed. Relatively undigested scales from 31 stomachs were stained with alizarin red and compared with a reference collection of scales from the fishes of the general collection (Fig. 2). In this sample 183 scales were clearly recognised as from *Astyanax* and *Curimatus*. It was not possible to identify with certainty the remaining, more digested scales, but only eight were of the ctenoid type (attributable to *Tilapia*) while all others, about 600, were cycloid of the *Astyanax* and *Curimatus* type. Other food items included plant material and insects.

The four live fish (64–82 mm) were maintained separately in aquaria (50–160 l) and used in observations of feeding behaviour. In one series of observations two to four individuals of *Astyanax* (36–115 mm) were placed together with

each *Probolodus*, and the groups were observed in sessions of 15–40 min for about 40 h. Soon after the introduction of *Astyanax*, *Probolodus* shoaled with them, and at intervals fed on their scales. In the most frequently observed feeding strategy *Probolodus* followed closely an individual of *Astyanax*, manoeuvred itself obliquely to the rear of the victim and struck at its flanks, securing one to a few scales on each successful attack. The scales seemed to be removed merely by a gaping and closing of the mouth during the strike, sometimes accompanied by a quick lateral movement of the head. The scales were swallowed immediately and *Probolodus* resumed shoaling. During the first day or so *Astyanax* shoaled together with *Probolodus* and apparently failed to recognise it as a 'predator'. Subsequently, *Astyanax* avoided close proximity with *Probolodus* and, to a certain extent, with each other. This latter behaviour is perhaps the result of repeated attacks on the same individuals in the confinement of the aquarium. In natural conditions the possibility of recognising *Probolodus* as a predator would be diminished because attacks would be 'diluted' over a greater number of victims. Fish less than half the size of *Probolodus* individuals, or more than one and a half times as large, were unmolested, which suggests that prey of more or less the same size as the predator are preferred.

In other observations, two individuals of diverse species were introduced separately into the aquarium with a *Probolodus* individual. These species included the cichlid *Geophagus brasiliensis* (60–81 mm), the characid *Bryconamericus* sp. (50–55 mm), the cyprinid *Carassius auratus* (41–53 mm) and the poeciliid *Phalloceros caudimaculatus* (22–32 mm). After initial attacks both *Bryconamericus* and *Carassius* avoided the close presence of *Probolodus*, hid and needed to be pursued. Only the largest *Probolodus* (82 mm) attacked *Geophagus*, and to a much lesser extent than the other species, while the small *Phalloceros* went unmolested. The latter observation confirms the size preference shown previously by *Probolodus*. In a final series of observations, both *Astyanax* (two individuals) and *Geophagus* (one individual) were introduced into an aquarium with *Probolodus*.

Fig. 2 Number and size of 183 relatively undigested scales from stomach analyses of 31 individuals of *P. heterostomus*. Size extremes for each genus may be found in the same individual prey and also in the stomach of the same predator. Open columns, *Astyanax*; hatched columns, *Curimatus*.

After 24 h *Astyanax* had suffered much greater scale loss than *Geophagus*.

Taken together, the accumulated data provide support for the hypothesis of aggressive mimicry<sup>3,6</sup> in which *Astyanax* is the prey-model and *Probolodus* is the predator-mimic. First, *P. heterostomus* and *A. fasciatus* have a striking overall similarity to each other. Aquarium observations indicate that *Astyanax* tolerated *Probolodus* and failed to recognise it as a potential predator, at least until repeated scale-biting in the conditions of a small aquarium caused a break-down of the shoaling habit. Second, both species are sympatric in the Rio Paraibuna (and over the Rio Paraíba drainage) and apparently live in mixed shoals or in close proximity. The proportion of *Probolodus* individuals to *Astyanax* in these areas seems to be roughly 1:10 which again fits the mimicry requirements. Third, *Probolodus* is a specialised scale-eater with a preference for prey more or less its own size and which is closely followed and struck from the rear. Stomach analyses of individuals caught in the Rio Paraibuna show preponderance of *Astyanax* scales.

A comparable case of mimicry has been reported for the African scale-eating cichlid fish *Corematodus shiranus* which closely resembles and shoals with the cichlid species *Tilapia squamipinnis*<sup>7,8</sup>. In such cases, the mimicry of the predator apparently facilitates its predatory success by allowing it to maintain close proximity with its potential prey<sup>3-9</sup>. This is the classic tactic of the wolf in sheep's clothing. Even if *Probolodus* is not so selective as it seems from my data it may still be advantageous to have the appearance of an ubiquitous and harmless fish, to facilitate the approach to an intended victim. A comparable strategy is used by a bird of prey<sup>10</sup> and some marine fishes<sup>11,12</sup>.

As *A. fasciatus* is not found over the entire range of *Probolodus*, it is probable that in other major river drainages this latter fish associates with other similar species of *Astyanax* (in the Rio Ribeira do Iguape, *A. ribeirae* is a likely candidate) or even such tetragonopterines as *Deuterodon iguape* which also has the general appearance of *Astyanax*.

Drs P. E. Gibbs, E. O. Willis and P. Montouchet reviewed the manuscript and Dr H. E. Britski confirmed the identity of the fishes.

## A new insect chemosterilant isolated from *Acorus calamus* L.

PLANT extracts have been tested for insecticide and juvenile hormone<sup>1</sup> activity and some have been found with anti-juvenile hormone activity<sup>2</sup>. We have suggested<sup>3,4</sup> that an essential oil of *Acorus calamus* L. inhibits interstitial cell activity; this would represent a new concept in insect chemosterilisation. We report here the identification of the component of the oil that is responsible for that inhibition; we have also established the

importance of substitute groups and a side chain by testing various allyl benzene analogues.

Using procedures described before<sup>3,4</sup>, we tested 3rd, 4th and 5th instar nymphs and the adults of *Dysdercus koenigii* for the efficacy of the inhibitory agent. Victoria blue<sup>5</sup>, aldehyde fuchsin<sup>6</sup> and Sudan black B were used to test for the appearance of neuro-secretory cells and interstitial cells (IC). Farnsyl methyl ether (FME), a juvenile hormone analogue, was given topically (10 µg and 12 µg per insect) to the insects before and after treatment with the candidate oil to reveal any physiological reversal.

*Acorus calamus* oil seemed to affect the various larval stages differently. While 3rd and 4th instar larvae moulted normally to the next instars, the 5th instar larvae moulted normally into adults but the ovaries were irreversibly affected. In such adults the ovary remains permanently immature (Fig. 1a). Longitudinal section through such an ovary revealed a well developed tropharium but a small vitellar region (Fig. 1b), composed only of interfollicular tissue, and no organised follicles. Isolation of the active principle<sup>7</sup>, β-asarone (Fig. 2, I) showed that it brought about a similar inhibition. The compound caused resorption in many gravid insects leading ultimately to complete regression of the ovaries. To find which of the substituent groups in the aromatic ring or the side chain of β-asarone was specifically inhibitory, trials were done with different allyl benzene compounds (Fig. 2). A wide spectrum of activity was observed (Table 1).

Table 1 shows that compound I severely depressed the development of the gonads. The neuro-secretory cells (NSC) revealed by both Victoria blue and aldehyde fuchsin were scored according to Schooneveld<sup>8</sup> and Johnson *et al.*<sup>9</sup>. The studies revealed no inhibition in the NSC's and the density of granules was nearly equal to that in controls. In cases where higher dosages (above 30 µl per 1,500 cm<sup>3</sup> of air space) were tried, however, a mild inhibition in the secretion from NSC was observed. There is no reason to suppose that NSC activity is involved in the chemosterilant action of β-asarone, because it has been reported that extirpation of the NSC within 30 h of the moult to adult does not affect subsequent vitellogenesis in *D. cingulatus*<sup>10</sup>.

Because the treated insects showed a normal moulting pattern we conclude that the oil does not adversely affect ecdysone release. As previously shown<sup>11</sup>, on treatment with higher doses, the moulting insect becomes lethally entangled in its own half cast moult. This may be because the larger dose of oil inhibits the release of secretion by NSC, which then delays the release of ecdysone and thus seriously impedes ecdysis.

**Fig. 1** a, Ovary of 6-d-old adult treated with *Acorus* oil. Note the well developed germarium and oocytes as spherical bodies in vitellar cavity. × 15. b, Longitudinal section through the ovariole of above ovary. Note the well developed tropharium (g) a short vitellarium (v) and oviduct (o) × 75.

Fig. 2 Structural formulae of compounds used.

The anti-juvenile hormones precocene I and II possess a significant measure of structural similarity with  $\beta$ -asarone, and both types of compound cause sterility in adult female insects. But they probably have different modes of action. Thus precocenes are believed to act by blocking the synthesis and release of juvenile hormones, which leads to the formation of precocious adults when the larvae of sensitive species are treated<sup>2</sup>. By contrast,  $\beta$ -asarone did not cause precocious metamorphosis in *D. koenigii* in our experiments. Furthermore, we observed no physiological reversal of the  $\beta$ -asarone effect on insect gonads when FME was applied topically to the insects before or after  $\beta$ -asarone treatment. These observations were made on adults up to 7d after moulting, which coincides with the first oviposition of control insects.

The molecular structure of the effective compound from oil of *A. calamus* is given in Fig. 2 I. The position of different groups in the aromatic ring is known to play an important part in various activities, as shown by some allelochemicals<sup>1,2</sup>, where the position of the hydroxyl groups is responsible for activities such as anti-assimilation and reduction of survival or pupation. Similarly in our study the position of the *O*-methyl groups on the ring, and of the double bond in the side-chain of  $\beta$ -asarone, plays an important part in the antigonadal activity (Table 1, Fig. 2). After testing the various compounds it was found that the *O*-methyl group at position R in the ring (Fig. 2, V) is important for the resorption of the oocytes, which is further supported by the suppression in the ovary due to the *O*-methyl group at R<sub>2</sub> (as in Eugenol, VI and methyl isoeugenol, III—Fig. 2). The suppression in the ovary due to the *O*-methyl group at R<sub>2</sub> seems true of precocene II<sup>2</sup> also because the removal of the *O*-methyl group from R<sub>2</sub> position in that molecule also reduces activity (precocene I of Bowers<sup>2</sup>). Comparison of the activities of compounds I and II (Table 1) suggests that the *cis* configuration of the side-chain double bond in  $\beta$ -asarone is important for antigonadal activity. It is interesting, however, that III which has a *trans* configuration, but lacks the *O*-methyl group at position R also has significant suppression activity.

Table 1 Activities of test compounds

Compounds	Activity		
	10 $\mu$ l per 1,500 cm <sup>3</sup> air space	20 $\mu$ l per 1,500 cm <sup>3</sup> air space	30 $\mu$ l per 1,500 cm <sup>3</sup> air space
I	Antigonadal	Antigonadal	Antigonadal
II	Nil	Nil	Nil
III	Nil	Mild yolk deposition*	Antissimulant + no yolk deposition
IV	Nil	Toxic	Toxic
V	Nil	Nil	Antigonadal
VI	Nil	Antissimulant + no yolk deposition	Toxic
VII	Nil	Nil	Nil
VIII	Nil	Nil	Nil
IX	Antifeedant	Toxic	Toxic
X	Nil	Nil	Nil

An antigonadal compound sterilised either sex, agglutinated sperm and caused resorption from terminal oocytes to apex of vitellarium. In antissimilants the alimentary canal was full and the fat body highly reduced and in antifeedants the alimentary canal was always empty.

\*Mild yolk deposition: the effect was the same in all oocytes.

We conclude that  $\beta$ -asarone is neither a juvenile hormone, nor an anti-allatotrophic compound (precocene I and II of Bowers<sup>2</sup>), and with its specific antigonadal functions, it may represent a new type of antigonadal agent which may afford a new and safe approach towards insect control.

We thank Dr P. L. Duda, Reader (Jammu University) for reading the manuscript, and Dr M. Jacobson of USDA for providing reference compounds.

## Assignment of aberration breakpoints in banded chromosomes

CHROMOSOME banding techniques<sup>1–4</sup> have made possible not only the detection but also a more accurate characterisation of the structural chromosomal changes encountered in clinical and experimental work. Using internationally agreed band patterns and nomenclature<sup>5</sup>, it is customary to assign breakpoints to aberrations such as translocations on the assumption that these 'breakpoints' correspond to the positions of breakage and rejoining which gave rise to the configuration observed. This assumption is frequently invalid, because it does not seem to be generally realised that the system carries (at least for chromosome-type exchanges) an inherent three-band uncertainty. This means that the most obvious breakpoint is not necessarily the site of transfer or rearrangement of the genetic material.

The assignments of 'breakpoints' is essentially an exercise in pattern recognition. Presented with a linear array of alternating dark and light segments against a light background (for example, a typical G-banded chromosome set viewed with conventional light microscopy), the human eye automatically concentrates on the disposition of the dark bands. We are much more conscious of differences in size, spacing and staining intensity of dark bands than of light bands although such differences occur in the latter.

Interruptions or breaks in an expected sequence are therefore interpreted in terms of the dark band pattern, and the pattern disruption point (PDP) will be assigned to a light band. Figure 1 illustrates this for a 6:10 human reciprocal translocation using the Paris Conference (1971) diagrams and nomenclature<sup>5</sup>. The left-hand pairs represent the G band patterns of the normal and derivative chromosomes. Obvious pattern disruption occurs at 6q21 and 10q22, that is a light/light-band exchange. But, essentially the same pattern (and derivative chromosome lengths and arm ratios) could be achieved by dark/dark-band exchanges on either side of this light-band, that is 6q16/10q21 or 6q22/10q23, but because of the eye's preoccupation with dark-bands, this is not immediately obvious.

This three-band uncertainty becomes clear when the same translocation is R banded<sup>6</sup>, a technique whereby the Giemsa staining of the bands is reversed in a more or less reciprocal manner (Fig. 1, right-hand pairs). The eye transfers attention to the new

Fig. 1 The derivative chromosomes of a human 6:10 reciprocal translocation compared with normal homologues. Left-hand pairs, G-band pattern; right-hand pairs, R-band pattern. Arrows indicate the pattern disruption points (PDP), and the three-band uncertainty zone is bracketed.

dark-band sequence so that the PDP again falls in a light band. This corresponds to one or other of the dark G bands which make up the trio of uncertainty. The breakpoint seems to have jumped a band, but only as the result of an optical artefact; it is not necessary to infer that exchange at a band junction is involved<sup>7</sup>. In the example of Fig. 1, the choice of PDP depends on the assessment of the R dark bands 6q21 and 10q22. Relative size differences are obvious in the diagram, and careful measurement will probably implicate 6q21 and 10q22 as the most likely breakpoint positions. In the real cell, such differences are seldom obvious, as we are working near the limits of optical resolution, and the quality of the banding is rarely uniform throughout the chromosome complement, so that homologue differences are often present.

In clinical work, where a particular translocation can be examined by different techniques and in several cells, subtle differences in size, staining intensity and conformation, impossible to depict in a diagram, may allow assignment of the breakpoint with reasonable certainty, but not in every case. In experimental work, particularly with primary chromosome-type changes, usually only one example is available, and the three-band uncertainty frequently remains. Where uncertainty exists it may be safer to use a more non-committal term like PDP.

It is often said that most chromosome-type exchange breakpoints occur in G light-bands (or weak fluorescing bands which are mostly identical to light bands)<sup>8-11</sup>. This could be largely an artefact of pattern-recognition.

Non-exchange aberrations such as simple terminal deletions do not, however, have the three-band uncertainty. This is also the case for most chromatid-type aberrations, because sister-chromatid pairing affinity ensures a banded 'control' chromatid in close proximity to the exchange point. Thus band-for-band comparisons can be made<sup>12-14</sup>. When this is done for X-ray-induced exchanges there is a clear indication of more or less exclusive light/light band involvement.

Free participation of both dark and light bands should lead to ~ 50% dark/light-band exchanges, which would be recognised by the creation of an extra dark band in one of the derivative chromosomes. Such cases seem to be very rare, implying that either exchanges are predominantly light/light or dark/dark or that partial bands are unstable and tend to merge with bands adjacent to the point of exchange. A similar argument applies to exchanges involving band junctions, interfaces<sup>15</sup>, or 'interbands'<sup>7</sup>. A high frequency of free interface/interface exchange would produce frequent band fusion in one derivative and concomitant band loss in the other. Such events are seldom seen.

Terms like band 'interface' and 'interband' should be used with caution. Sharp dark/light band junctions only exist on diagrams. The metaphase chromatid is a coiled<sup>16</sup> or double-coiled<sup>17</sup> structure, and there have been several suggestions that bands and coils are related<sup>18-20</sup>. Thus a transverse line across a chromatid will

run more or less parallel to the pitch angle of the coil, and is therefore unlikely to represent a sharp boundary for breakage purposes.

## *Tetrahymena pyriformis* recovers from antibody immobilisation by producing univalent antibody fragments

MANY protozoa possess mechanisms by which they are able to recover from immobilisation by specific antibodies. Paramecia have been shown to shed their ciliar antigens in response to specific divalent antibodies. After shedding the antibody bound antigens the animals present new antigens of different specificity<sup>1</sup>. It has been suggested that this modulation process also has a role in antigen variation in trypanosomes<sup>2</sup>. While modulation of serotypes in *Tetrahymena pyriformis* is primarily provoked by temperature shifts or changes in culture conditions<sup>3</sup>, induction of modulation in response to antibody agglutination has been reported<sup>4,5</sup>. *Tetrahymena* recovery from antibody provoked immobilisation has also been reported to occur by a nonspecific process not involving a change in serotype. Immobilised animals have been shown to secrete a substance which permits their recovery and protects animals of unrelated serotype from homologous anti-serum<sup>6-8</sup>. We have further examined the way that *Tetrahymena* recover from antibody provoked immobilisation. This process, which we call fabulation, apparently involves the proteolytic cleavage of both bound and free immunoglobulin to produce univalent fragments which bind or remain bound to the ciliar antigens and protect the animals from further antibody treatment with no apparent effects on cell growth. The cleavage seems to be catalysed by both cell bound and secreted proteases.

When *Tetrahymena* of syngen 9 are treated with specific antisera they are rapidly immobilised and often agglutinated. Rabbit antisera to *T. pyriformis* were prepared either by the method described in ref. 4 or by two intradermal injections of  $5 \times 10^5$  animals in complete Freund's adjuvant at 6-week intervals, followed by two intravenous injections of  $10^4$  sonicated animals at 2-week intervals. Rabbits were bled 6 d after the last injection. Immobilisation and agglutination tests were performed as described in ref. 4, except that the cell concentration was 2–4,000 per ml.

We have observed that when immobilised animals are left at room temperature for 1–2 h in the presence of antiserum all the animals are found to have recovered and swim freely. Further treatment of the recovered animals with antiserum of the same specificity has no effect. Also, addition of antiserum directed to other serotypes which the animals are capable of expressing has no effect. The possibility that the recovered animals had modulated their serotype and presented a hitherto unknown antigen was tested by injecting the recovered animals into rabbits. We found, however,

**Fig. 1** Effect of *Tetrahymena* cells on  $^{14}\text{C}$ -labelled mouse immunoglobulin.  $^{14}\text{C}$ -labelled mouse immunoglobulin, prepared by incubating spleen cells from trypanosome infected mice in a mixture of  $^{14}\text{C}$  amino acids, was a gift from Dr B. Bernstein.  $10^4$  *Tetrahymena* grown as described in ref. 6 were incubated with  $5\ \mu\text{l}$  of  $^{14}\text{C}$ -immunoglobulin (12,000 c.p.m.) in  $10^{-2}\text{M}$  phosphate buffer pH 7.5 containing  $10^{-3}\text{M}$  EDTA and  $10^{-3}\text{M}$  dithiothreitol. After 1 h at  $37^\circ\text{C}$ , 2 volumes of  $2\times$  sample $^{12}$  buffer were added and the samples were boiled for 2 min. They were then analysed by electrophoresis on 10% polyacrylamide gels as described by Laemmli $^{13}$ . The gels were dried and autoradiographed. The left lane represents the immunoglobulin preparation incubated without *Tetrahymena* cells. The right lane represents the preparation incubated with the cells.

that this resulted only in the production of very weak sera against the original serotype. It thus seems unlikely that the animals recover by a process of modulation of their ciliar antigens. If the recovered animals are cultivated in antiserum free medium (containing normal rabbit serum in the place of anti-*Tetrahymena* rabbit serum) they become sensitive to the original antiserum within 2–3 generations. The animals can also be rendered sensitive to the original antiserum by exhaustive washing. It seems, therefore, that the recovered animals are protected from the action of further antibodies.

*Tetrahymena* contain and excrete several proteases amongst which is an enzyme resembling papain $^{9,10}$ . As papain is known to cleave IgG of various mammalian species to produce Fab fragments $^{11}$ , it seemed possible that the *Tetrahymena* recover from antiserum treatment by specific cleavage of the antibodies by the papain-like enzyme and production of Fab-like fragments capable of binding to the antigens. These bound univalent fragments would then protect the animals without apparently deranging them. If such a mechanism were responsible for the recovery of *Tetrahymena* from antibody agglutination it would be expected that the recovered animals should be sensitive to agglutination by antibodies specific for the immunoglobulin originally used to agglutinate them and from which they had recovered. Furthermore, antibodies specific for the non-antigen binding fragment, or Fc, would not be expected to have an effect on the recovered animals. To test these predictions animals were treated with

specific rabbit anti-*Tetrahymena* serum and allowed to recover. The recovered animals were then washed once and treated with either sheep anti-rabbit total IgG (SaRIgG) or with sheep anti-rabbit Fc (SaRfFc). It was seen that treatment of the recovered animals with SaRIgG resulted in re-agglutination whereas treatment with SaRfFc had no effect. SaRIgG treatment of animals grown in pre-immune rabbit serum or in the absence of serum had no effect. Incubation of the reagglutinated animals again resulted in recovery, showing that sheep IgG is also sensitive to the *Tetrahymena* enzyme(s).

To demonstrate the cleavage of IgG by *Tetrahymena*  $^{14}\text{C}$ -labelled mouse IgG was incubated at  $37^\circ\text{C}$  in the presence of  $10^{-3}\text{M}$  EDTA and  $10^{-3}\text{M}$  dithiothreitol with washed *Tetrahymena* organisms. This treatment did not affect the viability of the organisms. After incubation the samples were analysed by SDS polyacrylamide gel electrophoresis. The gel was then dried and autoradiographed. The results are shown in Fig. 1. It can be seen that the light chain of the IgG was not degraded by the cells. The heavy chain was almost completely lost and replaced by two closely spaced bands which migrated just behind the light chain. The preparation of  $^{14}\text{C}$ -labelled mouse immunoglobulin also contained a small quantity of IgM. It can be seen that the  $\mu$  chain also disappeared after treatment with the cells although it is not known whether Fab was produced from the IgM. Similar results are seen when the immunoglobulins are incubated with *Tetrahymena* culture supernatants.

It seems clear from these observations that *Tetrahymena* of syngen 9 can recover from antibody agglutination by cleavage of the antibodies to produce univalent fragments which remain bound to the antigens and protect the animals from the effects of further antibody treatment. This 'fabulation' process suggests an efficient mechanism by which parasitic protozoa might escape the host immune system. Cell-bound univalent antibodies would be expected to have two effects: they would block antigenic sites from antigen sensitive cells, thus reducing the host's immune response, and they would protect the parasites from circulating antibody. Furthermore, cell-bound Fab would not activate complement.

## Isolation of a human teratoma cell line which expresses F9 antigen

THE F9 antigen, defined by antisera raised in syngeneic mice against pluripotent embryonal carcinoma cells, is present on early mouse embryos, spermatozoa and male germinal cells, but not on adult somatic tissues $^{1,2}$ . This antigen, thought to be coded by gene(s) located at, or linked to, the developmentally important *T/t* complex, may play a part in early embryogenesis $^{3-5}$ . This idea is supported by the fact that the antigen seems to have been conserved during mammalian evolution. Anti-F9 activity is absorbed by sperm of several

species including man, rat, rabbit and bull<sup>3-7</sup> and there is evidence for its presence on the morulae of rabbit, rat and cow, and on human foetal testicular cells<sup>2,5</sup>. The cross reaction of anti-F9 with human sperm suggested that undifferentiated stem cells in human teratocarcinomas might also carry F9 on their surface, and we report here the isolation of human teratocarcinoma cell line which expresses F9 antigen.

The cell line, known as SuSa, was isolated from a 30-yr-old male with a malignant testicular teratoma, intermediate grade B with extensive necrosis. Sections of the primary tumour had areas of undifferentiated cells in convoluted epithelial sheets, networks and vesicles, surrounded by simple tumour mesenchyme; limited areas of more differentiated cells, including keratinised and glandular epithelium and cartilage were also present. The patient had

**Fig. 1** Morphology of SuSa cells in culture. Pieces from different sites in the primary tumour were minced finely with scissors and placed in a 90-mm dish containing a monolayer of  $3 \times 10^6$  STO mouse feeder fibroblasts<sup>8</sup> in Dulbecco's modified Eagle's medium (MEM) with 10% calf and 10% foetal bovine serum. After about 5 d small patches of closely packed, homogeneous cells were seen, and after 2 weeks these were subcultured with 0.05% trypsin-0.5 mM EDTA in phosphate-buffered saline (PBS), pH 7.2. The cells have a very low plating efficiency (about 4%) even on feeder layers. Feeder layers were prepared by treating STO cells before plating out with mitomycin C ( $20 \mu\text{g ml}^{-1}$ ) for 2-3 h and 6,000-10,000 rad X rays. *a*, A vesicle in the centre of a colony of cells growing at high density on a feeder layer. Phase contrast microscopy; bar represents 100  $\mu\text{m}$ . *b*, Section through a chain of vesicles detached from a high density culture. Stained with haematoxylin and eosin, bar represents 50  $\mu\text{m}$ . *c*, Cells growing out from a vesicle which had attached to a tissue culture dish in the absence of feeder fibroblasts; bar represents 100  $\mu\text{m}$ .

**Fig. 2** Absorption of anti-F9 activity by SuSa and other human cell lines and mouse STO fibroblasts. Anti-F9 serum was elicited by hyperimmunisation of male 129/Sv mice with irradiated cells of the mouse teratocarcinoma line F9-41<sup>1</sup>, and was absorbed before use with cells of the parietal yolk sac line PYS2 and with human fibroblast (skin) cells (v/v, serum diluted 1/5 in Hanks medium containing 4% heat-inactivated  $\lambda$  globulin-free foetal bovine serum (IPT), for 1 h at 0 °C). Such absorbed sera are active against F9 cells in both the microcytotoxicity test (90-95% of cells killed at titres of 1/2400-1/3200) and the indirect immunofluorescence assay (90-100% of the F9 cells labelled at dilutions up to 1/400). Absorptions were made with 100  $\mu\text{l}$  of anti-F9 sera diluted 1/300 in Hanks medium + 4% IPT. After absorption with  $8 \times 10^6$  SuSa cells or  $1 \times 10^7$  cells of all the other cell lines tested at 4 °C for 1 h, the cells were removed by centrifugation and the residual cytotoxic activity was tested on F9 cells using serial dilutions in the presence of absorbed rabbit serum as a source of complement<sup>1</sup>. ●, Unabsorbed serum; □, absorbed on SuSa; △, absorbed on Burkitt's lymphoma<sup>9</sup>; ▲, absorbed on an intestinal cell line (American Type Culture Collection CCL6); ×, absorbed on an epidermal larynx tumour (ATCC CCL23); +, absorbed on HeLa (ATCC CCL2); ▼, absorbed on melanomas<sup>10</sup>; ⊗, absorbed on a rhabdomyosarcoma (ATCC CCL136); ○, absorbed on STO mouse fibroblasts.

multiple metastases and high levels of human chorionic-gonadotropin in the urine. HLA typing of the patient's peripheral blood lymphocytes was A1, A3, B5, Bw17 and possibly Cw3.

The cells are maintained on feeder layers of mouse fibroblasts and have a low ratio of cytoplasm to nucleus, and prominent nucleoli. They grow as flat colonies of densely packed cells which gradually pile up at the edges and centre, forming chains of simple epithelial vesicles which float off into the medium (Fig. 1a). Similar vesicles are produced when SuSa cells are subcultured in the absence of feeder fibroblasts. When floating vesicles attach to the tissue culture dish, the cells migrate out and become flattened (Fig. 1c), but they do not continue to grow when subcultured in the absence of feeder fibroblasts. In sections of fixed and stained material (Fig. 1b) SuSa cells closely resemble the undifferentiated epithelial cells of the primary tumour. In the electron microscope they show very little endoplasmic reticulum but have some microvilli and lipid droplets, and are joined by junction complexes. No virus particles have been seen.

Approximately 10 passages after its isolation the cell line had a modal chromosome number of 58, and its human origin was confirmed by the presence of metacentric chromosomes. Quinacrine mustard staining showed one Y chromosome in most spreads.

Absorption of anti-F9 serum with  $8 \times 10^6$  SuSa cells removed cytotoxic activity towards F9 cells (Fig. 2). Further experiments showed that as few as  $3 \times 10^6$  SuSa cells could remove most of the anti-F9 activity of the sera in the conditions described in Fig. 2. Anti-F9 activity was not absorbed by the STO cells used as feeders, nor by any of the human cell lines tested—HeLa, two Burkitt tumours,

two melanomas, an epidermal carcinoma of the larynx and an embryonal rhabdomyosarcoma.

In immunofluorescence studies (Table 1) anti-F9 serum reacted strongly with about half of the SuSa plus feeder cell population, but marked neither human nor mouse fibroblasts. No fluorescence labelling was observed after absorption of the serum by F9 cells or human sperm. Because mouse embryonal carcinoma cells which are F9 positive do not express H2 antigens or  $\beta_2$  microglobulin<sup>8</sup> we tested SuSa cells for the products of the major histocompatibility HLA locus in man. We found that only a very small percentage of SuSa cells was labelled by specific HLA-A1 or B5 antisera. The percentage of cells that bound anti-human  $\beta_2$  microglobulin in serum correlated well with the percentage of HLA positive cells. Together with the absorption studies, these results show that cultured SuSa cells express an antigen which cross-reacts with the F9 antigen on mouse embryonal carcinoma cells and human sperm, and that this expression is not due to the presence of STO feeder cells. Furthermore, most cells expressing the F9 antigen do not express HLA antigens, and judging by the presence of HLA antigens, only a minority of the human cells in the cultures seem to be differentiated.

Table 2 shows the results of double immunofluorescence labelling. When anti-F9 and a specific anti-HLA-B5 serum were used simultaneously all F9 positive cells were HLA-B5 negative, and *vice versa*. The result was similar when a rabbit anti-HLA serum was used in combination with anti-F9, suggesting mutual exclusion of F9 and HLA antigens on the SuSa cells. Double labelling with anti-F9 and an anti-human  $\beta_2$  microglobulin serum revealed that all F9 positive cells were  $\beta_2$  microglobulin negative. The human nature of the F9 positive cells in the SuSa population was confirmed by

See Table 1. Anti-human fibroblast serum was raised in rabbits immunised with three injections of human skin fibroblasts from a single donor. The serum was absorbed on mouse liver and spleen and on the mouse fibroblast line STO to render it specific. This serum is active on both HLA positive and HLA negative (Daudi) human cell lines. It was used at a dilution of 1/2,000 and revealed with goat anti-rabbit TRITC or FITC.

a double labelling experiment using anti-F9 and a pre-absorbed rabbit anti-human fibroblast serum. All F9 positive cells were labelled by this serum.

The studies described so far involved dissociated single cells. When intact aggregates were tested for F9 using methods applied to preimplantation embryos<sup>4</sup>, about 30% of them were marked by anti-F9 antiserum. When aggregates were dissociated before exposure to antiserum, 50–55% of the cells were F9 positive while about 80% were marked by anti-human fibroblast serum.

Several lines of evidence suggest that SuSa cells are equivalent to the undifferentiated stem cells of human testicular teratocarcinomas. First, most of them resemble morphologically the undifferentiated epithelial cells of the original tumour and other testicular teratomas<sup>11–13</sup>. Second, most of them express an antigen which cross-reacts with the F9 antigen on mouse embryonal carcinoma cells, and third, they do not express, or have available for reaction, products of the major histocompatibility HLA locus or  $\beta_2$  microglobulin. Although a few HLA positive cells are found in SuSa cultures we have no conclusive morphological evidence that the cells differentiate *in vitro*, nor can we exclude the possibility that the cells are differentiating into cytotrophoblast, which may not express HLA antigens. Proof of the tumorigenicity and stem cell nature of SuSa cells would be unambiguous if single cell clones gave rise to differentiated tumours in nude mice. But when eight nude mice were each injected subcutaneously with  $1 \times 10^6$  SuSa cells, no tumours developed after 2 months. In earlier experiments, cells taken directly from five primary testicular teratomas and one ovarian teratoma were tested for F9 by absorption and found to be negative (Buc. G. Gachelin and M.F. unpublished results). This may have reflected the small proportion of undifferentiated stem cells in the tumours tested but we cannot formally exclude the possibility that SuSa cells have acquired F9 expression *in vitro*.

Our results and those of Holden *et al.* (see following communication)<sup>14</sup> who find F9 on another line of human teratocarcinoma cells, Tera I, raise the possibility of looking for circulating autoantibodies in patients with testicular teratoma (and possibly seminoma), using cell lines such as SuSa, Tera I and F9 as targets.

We thank Drs D. J. Fairlamb and J. E. McLaughlin for tumour material, Dr C. Barnstable for HLA typing, and Gillian McArthur, Simone Lacaille and Colette Chereau for technical assistance. We also thank Phillippe Dubois for

**Table 1** Immunofluorescence studies on cell line SuSa, human fibroblast HLA-B5 and mouse fibroblast STO

Antisera used	% Cells fluorescing		
	Human teratoma SuSa	Human fibroblast HLA-A1 or HLA-B5	Mouse fibroblast STO
Anti-F9 + goat anti-mouse FITC	48,46,44,50	0	0
Anti-F9 preabsorbed on F9 + goat anti-mouse FITC	2	0	0
Anti-F9 preabsorbed on human sperm + goat anti-mouse FITC	4	0	0

$5 \times 10^6$  cells were centrifuged in a microfuge (Beckman Instruments Palo Alto). The pellet was resuspended in 50  $\mu$ l of antisera at an appropriate dilution in MEM+4% IPT and kept at 4 °C. After 45 min the cells were washed with the same medium and suspended in an anti-IgG globulin labelled either with fluorescein isothiocyanate (FITC) (Hyland) or with tetramethyl rhodamine isothiocyanate (TRITC). After 45 min at 4 °C, the cells were washed three times, resuspended in PBS pH 7.2, spread, air dried, fixed with methanol, then mounted in glycerol: PBS (80/20; v/v). Preparations were observed using a Leitz Orthoplan microscope. Appropriate specificity controls (normal and absorbed immune sera) were performed. Anti-F9 serum was used at a dilution of 1/80 and revealed by a goat-anti-mouse IgG and IgM, labelled with FITC. In the F9 controls, absorptions were made v/v with F9 antisera and cells for 1 h at 4 °C. Anti-HLA-A1 and anti-HLA-B5 were obtained from multiparous women. Anti-HLA-A1 was labelled directly with FITC. Anti-HLA-B5 was labelled directly with TRITC. Both sera were used at 1/25 dilutions and had been absorbed on mouse STO cells before use. The rabbit anti-HLA 5996-2 and the rabbit anti human  $\beta_2$  microglobulin sera (5895-21) raised against purified preparations of papain-solubilised HLA antigen and of human  $\beta_2$  microglobulin were given by N. Tanigaki. They were both preabsorbed with the Daudi lymphoma and STO cells before use. They were revealed with goat anti-rabbit IgG labelled with TRITC.

help, Drs C. Aubert and J. Pavie for cell lines and Drs J. Dausett and N. Tanigaki for antisera. Financial support was provided by the DGRST (M.F.) and INSERM (P.A.).

## Human and mouse embryonal carcinoma cells in culture share an embryonic antigen (F9)

THE embryonic membrane antigen F9 has been detected on several lines of mouse embryonal carcinoma (EC) cells as well as on mouse embryos and sperm, but not on any other adult cells tested<sup>1</sup>. F9 or an antigenically similar substance has been demonstrated on the morula and/or sperm of several mammalian species<sup>2</sup> including man<sup>3</sup>, but has been undetectable in all non-mammalian species tested<sup>2</sup>. Although no function for this antigen has been identified, its restriction to embryonic and germ cells suggests an important developmental role. This possibility is enhanced by the apparent conservation of F9 in the course of evolution. We now report the serological detection of F9 on human EC, together with our inability to detect  $\beta_2$  microglobulin.

We investigated two established tissue culture lines of human EC cells for the presence of F9 antigen. These lines (Tera I, Tera II) were cultured from the pulmonary metastases of two men with testicular teratocarcinoma<sup>4</sup>. *In vitro*, these EC cells seem morphologically similar to murine EC cells and do not exhibit visible differentiation in standard growth conditions. Attempts are in progress to characterise these lines by growing them in athymic mice. Using mouse anti-F9 antisera, we have shown in complement-mediated cytotoxicity assays and by absorption that F9 antigen is detectable on Tera II but not on Tera I (Figs 1 and 2). F9 could not be detected by similar techniques on normal human fibroblasts or on three human lines derived from lung, intestinal and skin tumours. It is interesting that in direct cytotoxicity tests, Tera II was almost as sensitive to anti-F9 antisera as its murine counterpart.

Immunoperoxidase studies confirmed the presence of F9 antigen on Tera II cells and also showed that F9 can be detected on a small fraction of the Tera I cell population (Fig. 3).

**Fig. 1** Complement-mediated cytotoxic activity of anti-F9 serum on F9 cells before absorption (1), after double absorption with human EC cells, Tera II (1), Tera I (3), human melanoma, MalME (4), human intestinal tumour HT 29 (5), human lung tumour SKMEM-1 (6) and murine yolk sac carcinoma PYS (7). F9 cells originated from Steven's OTT6050 teratocarcinoma; human cells were isolated and supplied by Føgh<sup>4</sup>. All cells were cultivated at 37 °C in 12% CO<sub>2</sub> in air as a monolayer on plastic Petri dishes in Dulbecco's modified Eagle's medium containing 15% foetal calf serum and 1% penicillin/streptomycin. F9 but not human cells were grown on a 0.1% gelatin layer. The preparation of antisera, complement and cells as well as the details of the cytotoxicity test are identical to the technique previously described<sup>1</sup> except that double absorptions performed at 4 °C for 45 min each utilising a 1:2 ratio of cell volume to serum volume were required for Tera II to remove anti-F9 activity. The absorptions were performed at a serum concentration of 2 doubling dilutions below the titre. Lines 1–3 represent the averages of three to nine independent experiments. Lines 4–7 represent single experiments. All complement and cell controls were between 10 and 22% dead.

Both EC and early embryo cells contain large quantities of alkaline phosphatase which decline with the onset of differentiation<sup>5</sup>. Although the function of this enzyme is unknown, it is a useful marker for cellular differentiation. We tested Tera I and Tera II for the presence of alkaline phosphatase by the method of Burstone<sup>6</sup>. Our findings that Tera II cells contained high levels of alkaline phosphatase plus F9 antigen while most Tera I cells lacked F9 antigen and had low alkaline phosphatase could be explained if most Tera I cells are more differentiated than Tera II.

Because mouse EC or embryonic cells that express F9 antigen lack H-2 (ref. 7), and H-2 becomes detectable with the onset of differentiation as F9 disappears<sup>8</sup>, we tested indirectly for the presence of HLA antigen on Tera II cells. Because we did not know the HLA type of the patients from whom these cells derive, we tested for the presence of  $\beta_2$  microglobulin, with which the HLA antigens are invariably associated. Complement-mediated cytotoxicity tests and absorption showed that Tera II did not express  $\beta_2$  microglobulin, while Tera I and other human cell lines tested did (Figs 2 and 4). This suggests not only that Tera II lacks HLA but also that it lacks the human counterpart of other mouse antigens such as TL and QA-2, which are also associated with  $\beta_2$  microglobulin in the membrane.

Two observations made in patients with testicular cancer suggest that human teratocarcinoma does not stimulate the host

**Fig. 2** *a*, Direct complement-mediated cytotoxic activity of murine anti-F9 serum on Tera II (1), F9 (2), SKMEM-1 (3), Ma1ME (4), Tera I (5), human fibroblasts (6) and HT29 (7). Lines 1-4 represent the averages of two to nine independent experiments. Lines 5-7 represent single experiments. Complement controls averaged 23.8% dead and were all below 30%. Cell controls averaged 16.4% dead and were all below 25%. *b*, Direct complement-mediated cytotoxic activity of rabbit anti-human  $\beta_2$  microglobulin (DAKO-immunoglobulins code no. 10-U72, Dakopatts, Denmark) on Tera II (1), fibroblasts (2), Tera I (3), HT-29 (4), SKMEM-1 (5) and Ma1ME (6). Lines 1, 2 and 6 represent averages of two independent experiments. Lines 3-5 represent single experiments. Complement, serum and cell controls ranged from 9 to 28% dead and averaged 18.4%.

cellular immune response. First, unlike patients with virtually all other forms of cancer, those with testicular tumours in advanced stages demonstrate a grossly intact cellular immune system when measured by their ability to respond by delayed cutaneous

hypersensitivity to intradermal antigens such as dinitrochlorobenzene<sup>9</sup>. Second, unlike the case of patients with various cancers tested, the immunomorphological features of the regional lymph nodes in testicular cancer have not been correlated successfully with prognosis<sup>10</sup>. The lack of HLA on teratocarcinoma may explain these anomalies. For example, the absence of H-2 on F9 cells apparently prevents them from serving as target cells either for allogeneic cytotoxic T cells immunised against spleen cells syngeneic to F9, or for syngeneic T cells sensitised to trinitrophenyl- or virus-modified spleen cells<sup>11,12</sup>. It has been suggested that the phenotypic expression of H-2 genes by the target cell is necessary for cell-mediated immunity<sup>12,13</sup>. Thus T cells in regional lymph nodes of human patients may be unable to see EC cells because of their lack of HLA expression. This hypothesis, if correct, could have direct impact on plans for immunotherapy of this disease.

Because embryonic antigens (F9) stimulate a humoral or 'autoantibody' response in syngeneic systems, and human teratocarcinomas express F9 antigen, our current efforts are directed toward the detection of anti-F9 autoantibody in the sera of

**Fig. 3** Immunoperoxidase study of anti-F9 serum on human teratoma cell lines.  $1-2 \times 10^6$  cells were incubated for 60 min at  $+4^\circ\text{C}$  in 0.1 ml anti-F9 serum diluted 1:50 in Hanks medium supplemented with 5% heat-inactivated  $\gamma$ -globulin-free foetal calf serum (Gibco). Cells were washed three times in the same medium and resuspended in 0.1 ml of a  $65 \mu\text{g ml}^{-1}$  solution of peroxidase-labelled sheep Fab anti-mouse immunoglobulins (Institut Pasteur) for another 1 h at  $+4^\circ\text{C}$ . After three washings in medium, cells were fixed in 2% glutaraldehyde in phosphate-buffered saline (PBS), further washed in PBS and stained for peroxidase activity in diaminobenzidine (50 mg per 100 ml in Tris-HCl, pH 7.5) and 0.01%  $\text{H}_2\text{O}_2$  for 3 min at room temperature. *a*, Tera II cells incubated in anti-F9 antiserum, phase contrast micrograph. *b*, Tera II cells incubated in anti-F9 antiserum. A discrete labelling of the cell membrane was detectable in 80% of the cells. No labelling was present when anti-F9 serum had been previously absorbed on F9 cells. Absorption of anti-F9 serum on PYS cells did not alter the labelling observed with unabsorbed serum ( $\times 350$ ). *c*, Tera I cells incubated in anti-F9 serum. Most of the cells were unlabelled, but about 15% showed a membrane labelling sometimes stronger than that on Tera II cells. This labelling was no longer detectable with anti-F9 serum absorbed on F9 cells ( $\times 350$ ). When Ma1ME cells were incubated with the same anti-F9 serum, some cell membrane labelling could be detected. This, however, was not removed by absorption of anti-F9 serum on F9 cells.

**Fig. 4** Complement-mediated cytotoxic activity of rabbit anti-human  $\beta_2$  microglobulin on human fibroblasts before absorption and (2) after single absorption with Tera II (1), Tera I (3), HT 29 (4), SKMEM-1 (5) and Ma1 ME (6). Lines 1 and 3 represent the averages of two independent experiments. Lines 3-6 represent single experiments. All complement, serum and cell controls varied between 8 and 28% dead.

patients with testicular cancer. If present, this activity could serve as a highly specific biological marker of tumour activity.

## Murine pluripotential stem cells lack Ia antigen

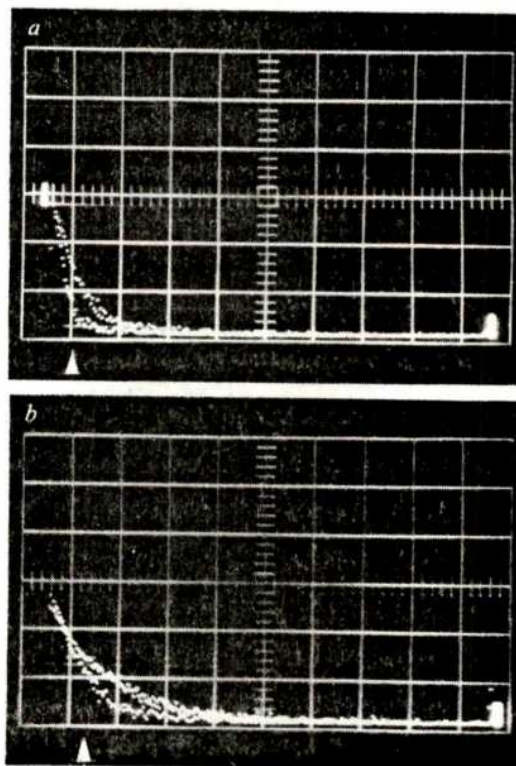

THE Ia (I region associated) antigens of the mouse were first described as differentiation antigens of B lymphocytes<sup>1,2</sup>. Subsequently, similar antigens, determined by the same or closely linked genes, have been found on macrophages<sup>3</sup>, on some T cells<sup>4</sup> and on stable products released by T cells<sup>5</sup>. Immunoprecipitated Ia antigen is a dimeric molecule, consisting of two dissimilar polypeptides<sup>6</sup>. The alloantigenic polymorphism of the structure is attributed to variation in the larger (33,000 molecular weight)

subunit. Evidence has accumulated suggesting that Ia antigens are involved in immunological recognition and/or cell interactions<sup>8,9</sup>.

Structures with similar biochemical properties have been identified on human cells and specific hetero- and allo-antisera against these Ia-like antigens are available<sup>10-14</sup>. The distribution of the human 'Ia-like' material on normal cells closely parallels that found in mice. Cells in chronic lymphocytic leukaemia and B type lymphomas have been found to be positive<sup>11-16</sup>. Unexpected and intriguing results were obtained, however, when the distribution of these antigens on leukaemic and foetal cells was studied. Most leukaemic lymphoblasts in patients with the common, non-T, non-B type of acute lymphoid leukaemia (ALL), myeloblasts in patients with acute myelocytic leukaemia (AML) and blast cells found in patients with chronic myeloid leukaemia in blast crisis (CML-BC) expressed a Ia-like antigen which was completely cross-reactive with B cell Ia (refs 14-16). More mature myeloid cells (myelocytes and granulocytes) on the other hand were Ia negative<sup>16,17</sup>. Ia positive, membrane immunoglobulin negative, lymphoblasts, myeloblasts and in some cases promyelocytes, were also found in non-leukaemic adult and foetal bone marrow cells<sup>16,17</sup>. On this basis it was suggested that 'Ia-like' antigens on blast cells in acute leukaemia may reflect their origin from Ia positive haematopoietic stem cells<sup>16,17</sup>.

A direct assay for cells which serve as a precursor to both lymphocytes and granulocytes is not available in man. These pluripotential stem cells can, however, be quantified in the mouse. Transfer of limited numbers of haematopoietic cells into irradiated mice results in the formation of discrete nodules in the spleen<sup>18</sup>. These spleen colonies are the product of the clonal proliferation of pluripotential stem cells (CFU<sub>s</sub>). We have examined the effects of antisera to Ia antigens on the cells which give rise to spleen colonies.

**Fig. 1** FACS histogram analysis of Ia positive cells from mouse (CBA) bone marrow. *a*, A.TH  $\alpha$  A.TL compared with normal mouse (A.TH) serum; *b*, rabbit  $\alpha$  'Ia' compared with rabbit  $\alpha$  mouse Ig. The abscissa is fluorescence intensity in arbitrary units and the ordinate is the log of the frequency of detected cells. The white arrows indicate the points at which the division between Ia positive and negative cells were made. The settings of the sorter were: photomultiplier tube 600 V, laser, 400 mW, fluorescence gain 16:1, scatter gain 2/0.5.

The results in treating mouse bone marrow cells with polyvalent alloantiserum against Ia (A.TH  $\times$  A.TL) and complement are shown in the first experiment in Table 1. The anti-Ia serum did not reduce the number of colonies found. Line 3 of the Table shows that the CFU of CBA mice can be killed by antibody (rabbit anti-mouse brain) and complement in the conditions used. Since the failure of alloantiserum to kill is not proof of the absence of antigen, we used the fluorescence-activated cell sorter (FACS I) to separate Ia<sup>+</sup> and Ia<sup>-</sup> cells from mouse bone marrow and tested these cells for their ability to form spleen colonies. To prevent the complement mediated destruction of antibody-coated cells after their injection into the irradiated recipients the cells were incubated at 37 °C for 1 h in tissue culture medium RPMI1640 supplemented with 2% heat inactivated foetal bovine serum. This treatment effectively removes the antibody both as judged by fluorescence microscopy and by the recovery of CFU<sub>(s)</sub> from cells treated with rabbit anti-mouse brain (Fab<sub>2</sub>) and fluoresceinated goat anti-rabbit Ig (lines 10 and 11, experiment 2, Table 1). 14.1% of the total are Ia positive on the basis of the sorter analysis (compared to 6.0% when stained with normal mouse serum) as shown in Fig. 1a. Both the positive cells and the negative cells were collected and injected into irradiated recipients. The results are shown in experiment 2, Table 1. Almost all of the CFU<sub>(s)</sub> of C<sub>3</sub>H bone marrow was recovered in the Ia<sup>-</sup> fraction. The apparent activity of the Ia<sup>+</sup> fraction (line 8) can be accounted for by

**Table 1** Effect of anti-Ia alloantiserum on CFU<sub>(s)</sub> obtained from mouse bone marrow

Expt 1: negative selection with anti-Ia antiserum and complement

Antiserum	Volume per 10 <sup>6</sup> cells ( $\mu$ l)	Spleen colonies per 10 <sup>5</sup> cells injected	
1. Normal A.TH serum	50	17.4 $\pm$ 2.6	(14)
2. A.TH $\times$ A.TL	50	16.3 $\pm$ 3.5	(12)
3. Normal rabbit serum	20	15.8 $\pm$ 3.1	(5)
4. Rabbit anti-mouse brain	20	2.2 $\pm$ 1.7	(5)
5. No cells transferred	—	0.3 $\pm$ 0.1	(18)

Expt 2: Positive selection using FACS to obtain Ia<sup>+</sup> cells

Cells transferred	Number	Spleen colonies	
6. Unfractionated CBA bone marrow	100,000	18.2 $\pm$ 2.1	(9)
7. Ia negative fraction	100,000	15.6 $\pm$ 3.9	(8)
8. Ia positive fraction	50,000	5.8 $\pm$ 1.6	(4)
	15,000	1.7 $\pm$ 1.5	(5)
9. Unfractionated + NRS	100,000	14.0 $\pm$ 2.8	(5)
10. Unfractionated + R anti-MB + C	100,000	4.2 $\pm$ 2.6	(5)
11. Unfractionated + R anti-MB + goat anti-R1g incubated at 37 °C for 1 h	100,000	14.7 $\pm$ 4.0	(5)
12. No cells transferred	0	0.4 $\pm$ 0.2	(5)

Recipient mice (CBA in expt 1, C<sub>3</sub>H in expt 2) were irradiated with 750 R from a <sup>60</sup>Co source and injected intravenously with bone marrow cells suspended in tissue culture medium. The animals were killed 9 d later and the spleens removed and fixed in Bouins solution. The spleen colonies visible on the surface were counted under a dissecting microscope at 25 $\times$  magnification. In Expt 1, 10<sup>6</sup> bone marrow cells were incubated at 4 °C with 20–50  $\mu$ l of antiserum in a total volume of 250  $\mu$ l. After 1 h they were washed twice and then incubated for 30 min at 37 °C with guinea pig serum diluted 1:3. The cells were then washed twice, resuspended in media and 10<sup>5</sup> cells injected into each mouse. A.TH  $\times$  A.TL, prepared by Dr I. McKenzie, was obtained by Dr Marc Feldmann and had a titre of  $\sim$  1:50 against CBA spleen cells. R  $\times$  MB was prepared as previously described and had a titre of 1:200 (ref. 19). It had been absorbed with mouse red blood cells, liver and cortical thymocytes from CBA mice. In expt 2, 10<sup>7</sup> cells were incubated with 100  $\mu$ l of antiserum in a total volume of 250  $\mu$ l at 4 °C for 30 min, washed twice and then incubated for 30 min with 50  $\mu$ l of a 1  $\mu$ g ml<sup>-1</sup> solution of the fluoresceinated (Fab<sub>2</sub>) fraction prepared by pepsin treatment of the total immunoglobulins of rabbit anti-mouse Ig serum. They were then washed twice and passed through the FACS. All of the FACS-passed and control cells were adjusted to 10<sup>6</sup> cells ml<sup>-1</sup> and incubated at 37 °C for 1 h before being injected into the irradiated mice.

\*Values are means  $\pm$  s.d.; number of tests performed is given in parentheses.

**Table 2** Effect of heterologous antiserum to mouse Ia on the CFU<sub>(s)</sub> obtained from mouse bone marrow

Expt 1: negative selection with anti-Ia and complement

Antiserum	Volume per 10 <sup>6</sup> cells ( $\mu$ l)	Spleen colonies per 10 <sup>5</sup> cells injected	
1. Normal rabbit serum (pre bleed)	50	14.8 $\pm$ 1.6	(5)
2. 'Anti-Ia'	50	13.5 $\pm$ 2.8	(5)
3. 'Anti-Ia' absorbed with mouse Ig on BioGel bleeds	150	14.6 $\pm$ 1.9	(4)
4. Anti-mouse Ig	50	11.9 $\pm$ 3.5	(5)
5. Complement only	—	12.2 $\pm$ 2.6	(6)
6. No cells	—	0.2 $\pm$ 0.1	(4)

Expt 2: Positive selection

Cells transferred	Number	Spleen colonies	
7. Unfractionated CBA bone marrow	100,000	12.7 $\pm$ 3.1	(5)
8. 'Anti-Ia' negative cell	100,000	17.3 $\pm$ 4.2	(4)
9. 'Anti-Ia' positive cell	100,000	5.1 $\pm$ 2.7	(4)
10. No cells	—	0	

Condition as for Table 1. The 'anti-Ia antiserum' after exhaustive absorption with insolubilised Mlg stained  $\sim$  35% mouse spleen cells and  $\sim$  5% of mouse bone marrow cells at a dilution of 1:20 when developed with a fluoresceinated goat anti-rabbit Ig serum (Fab<sub>2</sub>).

contamination of the Ia<sup>+</sup> fraction with Ia<sup>-</sup> cells. The sorter was adjusted so that positive cells were excluded from the negative fraction but many cells which lacked Ia antigen were included in the Ia positive fraction.

Most of the studies of human 'Ia-like' antigens on human cells have used heteroantisera against Ia. Since these sera recognise only the non-polymorphic subunit<sup>7</sup> it is possible that only this portion of the molecule is present on the stem cells. They would thus escape detection by the alloantiserum used in the experiments reported in Table 1. To obviate this we have prepared a heterologous antiserum to mouse Ia antigens by injecting immunoprecipitates of Ia-alloanti-Ia complexes (precipitated with rabbit anti-mouse Ig) into rabbits. After four injections at 2-week intervals a serum was obtained which seems to contain anti-Ia antibodies. This serum, after exhaustive adsorption with insolubilised mouse Ig reacts with the majority of the Ig<sup>+</sup> cells of the spleen and bone marrow and also stains some Ig<sup>-</sup> cells from both organs. A detailed report of its properties will be presented elsewhere. Its effect on the mouse bone marrow cells which produce spleen colonies is shown in Table 2. In the first experiment the serum was added to CBA bone marrow cells with an effective source of complement and in the second FACS-separated C<sub>3</sub>H cells were injected: 19.6% of the cells are antigen positive compared with a background of 12.8% with normal rabbit serum (Fig. 1b). The results indicate that the cells identified by this heterologous antiserum to mouse Ia antigen are not CFU<sub>(s)</sub>. The serum does not kill CFU<sub>(s)</sub> and essentially all of the CFU are recovered in the 'Ia' negative fraction.

If these results can be generalised to man, it would seem that the cells recognised by the anti-'Ia' sera in human foetuses and in AML are not related to the most immature haematopoietic elements.

Ia antigens may only be expressed on progeny of these cells: cells which are already committed to either the lymphoid or myeloid cell lineages. Preliminary observations in man suggest that both Ia<sup>+</sup> and Ia<sup>-</sup> populations do contain myeloid precursors which form colonies when grown *in vitro* in semi-solid media (CFU<sub>(c)</sub>)<sup>20</sup> (G.J., X. Francis and M.F.G., unpublished). The basis for this heterogeneity has not been established but it seems possible that it is a consequence of the presence of cells of different degrees of maturity in the CFU<sub>(c)</sub> population.

Alternatively, it has been suggested that the expression of human Ia-like antigens is cell cycle dependent. CFU<sub>(s)</sub> in the mouse are not a mitotically active population. It is thus possible that

multipotential stem cells when driven into cell division might express Ia antigens but the resting cell normally present in the bone marrow seems to lack this antigen.

## Absence of suppressor cells from rats bearing passively enhanced kidney allografts

LYMPHOCYTES which inhibit the immunological responses of other lymphocytes are known as suppressor cells, and such cells have been shown to mediate both specific and non-specific unresponsiveness in many experimental situations<sup>1–3</sup>. In the context of allotransplantation, Kilshaw *et al.*<sup>4,5</sup> have found that the highly strain-specific unresponsiveness to skin allografts induced in adult mice by pretreatment with donor strain tissue extract and *Bordetella pertussis* vaccine, followed by a short post-operative course of antilymphocyte serum (ALS), is at least in part mediated by thymus-dependent lymphocytes. Thus, transfer of  $25\text{--}100 \times 10^6$  spleen cells (optimally the lower dose<sup>5</sup>) from mice in the stable phase of unresponsiveness into ALS-treated syngeneic recipients established a long-lasting unresponsiveness to donor strain skin grafts in up to 50% of recipients. Because the nature of the mechanisms of immunological enhancement of kidney allografts in rats remain unclear<sup>6–8</sup> we have carried out cell transfer experiments similar to those of Kilshaw *et al.* in order to discover whether suppressor cells also play a part in mediating the stable phase of the enhanced state. Fabre and Morris<sup>9</sup> have previously failed to transfer unresponsiveness with spleen cells from rats with enhanced kidneys, but it is possible that transfer of cells to normal, syngeneic rats—as in their experiments—is an insufficiently sensitive method for detecting suppressor cells. Our results show that it is unlikely that suppressor cells or auto-anti-idiotypic antibodies are responsible for the steady state of enhancement. A more likely explanation involves the induction of unresponsiveness by the continuous exposure of the recipient to histocompatibility antigens in the absence of Ia-like antigens—the latter determinants being obligatory requirements for the activation of T cells ‘help-

**Fig. 1** Survival of AUG skin grafts in ALS-treated AS males following transfer of spleen and lymph node cells from normal AS female rats or female AS donors that had received passively enhanced F1 kidneys 5–9 months before (experiment 1). Cells were injected i.p. on day 10, ALS s.c. on days 1, 3 and 6 (arrows). ALS dose, 4 ml per rat per injection: 8 rats per group. *a*, Received  $175 \times 10^6$  cells from donors with enhanced kidneys. *b*, Received  $25 \times 10^6$  cells from donors with enhanced kidneys. *c*, Received  $175 \times 10^6$  cells from normal donors matched for age and sex. *d*, Received  $25 \times 10^6$  cells from normal donors matched for age and sex. *e*, ALS controls.

ing’ both potentially reactive B cells and T cells capable of differentiating into killer cells.

Passive enhancement of (AS $\times$ AUG)<sub>F1</sub> kidneys transplanted orthotopically to AS strain recipients was induced by injecting the recipients with 0.15–1.0 ml of AS-anti-AUG alloantiserum. As described previously<sup>6,7</sup>, this treatment leads to the production of a stable unresponsiveness, the majority of recipients continuing to live indefinitely with normal or slightly raised blood urea levels. The cell donors used in the three transfer experiments described here had been sustained by their grafts for 5–14 months, with a mean of 8 months.

The design of the transfer experiments was essentially the same as that used to demonstrate the presence of suppressor cells in the long-term unresponsive mice described by Kilshaw *et al.*<sup>4,5</sup>. Adult AS rats were grafted with AUG strain skin allografts on day 0; rabbit anti-rat lymphocyte serum (ALS), raised by two intravenous injections of approximately  $10^9$  AS lymph node cells, was administered subcutaneously to these animals either on days 2, 4 and 6 or on days 1, 3 and 6 after transplantation (for details see figure legends). On day 9 or 10, lymphoid cell suspensions were prepared from the AS rats bearing enhanced kidney allografts and injected in varying numbers into the prepared recipients (intraperitoneally in experiment 1 and intravenously in experiments 2 and 3).

Spleen and lymph node suspensions for transfer were prepared by shredding the tissues with fine forceps in RPMI 1640 medium to which 5% foetal calf serum had been added. The coarse suspension was then sieved and clumps were removed by rapid passage through a cotton wool filter or by allowing the clumps to settle. The resulting single cell suspensions were centrifuged for 10 min at 1,200 r.p.m., resuspended, counted and assessed for viability.

The results were clear-cut. In experiment 1, neither high nor low doses of mixed spleen and lymph node cells transferred unresponsiveness, although 2/8 of the grafts in the high dose group exceeded the median survival time of the control grafts by 20–25 d (Fig. 1). High doses of normal cells somewhat curtailed graft survival, as might be expected. In the second experiment (Fig. 2) only 1/11 grafts in the group receiving spleen cells showed prolonged but limited survival beyond that of the controls; in the third (Fig. 3) there was no difference whatever between experimental and control groups. According to the Mann–Whitney test there were no statistically significant differences between the experimental and control group of experiments 1 and

2 ( $P = >0.05$ ). It must be concluded that splenic suppressor cells do not have a significant role in mediating the stable phase of the enhanced state, unless we have been singularly unfortunate in our choice of the number of cells transferred. The lower dose (Fig. 1) corresponds to that giving optimal results in mice<sup>5</sup>, and the higher dose was intended to take into account the body weight differences between mice and rats.

These experiments also provide evidence against the participation of auto-anti-idiotypic immunity in the 'steady state' of enhanced kidney allografts. Binz *et al.*<sup>10</sup> have shown that B- and T-cell recognition structures have idiotypes in common, and that anti-idiotypic antibodies will combine with subpopulations of T and B cells which react with the same transplantation antigens<sup>11</sup>. Because auto-anti-idiotypic antibody production can be provoked in Lewis rats either directly by immunisation with purified natural antibody<sup>12</sup> or with specifically reactive autologous T cells<sup>13</sup>, or indirectly by allogeneic tissue<sup>14</sup>, kidney allograft survival could be due to the development of auto-anti-idiotypic immunity<sup>15</sup>. Whilst auto-anti-idiotypic immunity can undoubtedly be induced in both mice and rats, and can cause a specific unresponsiveness<sup>16</sup>, it has yet to be shown that this is the major mechanism which protects kidney allografts during the steady state of enhancement. If auto-anti-idiotypic immunity were involved it should be possible to transfer the unresponsiveness adoptively with lymphoid cells, but our experiments show that this does not happen. Other evidence against the auto-anti-idiotypic hypothesis is provided by the finding that kidney allograft protection cannot be achieved convincingly by actively immunising AS rats with purified AS-anti-AUG antibody derived from enhancing sera<sup>7</sup>, despite the fact that in this strain combination enhancement can be brought about with relatively small doses of antiserum; and by the observation that passive immunisation of Lewis rats with Lewis anti-(Lewis-anti-BN) antibody only occasionally prolongs the survival of (Lewis × BN)<sub>F</sub><sub>1</sub> kidney allografts<sup>18</sup>.

If neither suppressor cells nor anti-idiotypic antibodies are primarily involved in mediating the stable phase of the enhanced state, what other mechanism is likely to be operative? Cantor and Boyse<sup>17</sup> have shown that T lymphocytes can be divided into at least two populations, one responding to Ia-like antigens and the other maturing into killer T lymphocytes with specificity for the classical histocompatibility (H) antigens. The Ia-responsive population of T cells provides help both for the B cell lineage, which synthesises IgG antibody against the thymus-dependent MHC antigens<sup>18,19</sup>, and the T-cell clones, which differentiate into

**Fig. 2** Survival of AUG skin grafts in ALS-treated AS females following transfer of spleen cells from female AS donors that had received their passively enhanced F1 kidneys 5–8 months before (experiment 2). Cells injected i.v. on day 10, ALS s.c. on days 1, 3 and 6 (arrows). ALS dose, 1.0 ml per 50 g body-weight per injection: 11 rats per group. *a*, Received  $200 \times 10^6$  cells from donors with enhanced kidneys. *b*, ALS controls.

**Fig. 3** Survival of AUG skin grafts in ALS-treated AS males following transfer of spleen cells from male AS donors that had received their passively enhanced F1 kidneys 9–14 months before (experiment 3). Cells injected i.v. on day 9, ALS s.c. on days 2, 4 and 6 (arrows). ALS dose, 1.0 ml per 40 g body weight per injection. *a*, Received  $200 \times 10^6$  cells from donors with enhanced kidneys (11 rats). *b*, ALS controls (13 rats).

killer T lymphocytes with specificity for H-type antigens<sup>20,21</sup>. Because kidneys contain little or no Ia-type antigen<sup>22</sup>, and long-surviving allografts must be devoid of donor-type passenger leukocytes, during the steady state of enhancement the recipient is exposed to a continuous presence of H-type antigen in the absence of stimulation by Ia. We postulate that this exposure not only fails to provoke immunity but also induces cumulatively a specific non-reactivity of the T and B precursor cells which, if provided with 'help', would normally have differentiated into T killers and antibody producers, respectively, with specificity for H-type antigens.

In keeping with this hypothesis is the finding that pretreatment of rats with allogeneic platelets leads to suppression rather than activation of humoral immunity<sup>23</sup>, for platelets possess H antigens but lack Ia. Consistent depression of killer T lymphocyte generation after platelet injection was not observed, but only a limited number of dose schedules have so far been examined. Because prolonged kidney allograft survival has been observed after pretreatment of recipients with platelets<sup>24</sup>, and Wagner and Nossal<sup>21</sup> have shown that cellular immunity generated *in vitro* can be specifically suppressed by allogeneic membranes provided that high doses are added to the cultures, the question of dosage effects *in vivo* clearly needs further examination.

It has been suggested that induction of enhancement is due to the opsonisation of antigen-reactive cells by antigen-antibody complexes and their subsequent removal through phagocytosis<sup>25</sup>. The maintenance of the steady state by this mechanism would require the continuous production of anti-donor antibody. Because the amount of antibody required for maintenance (as opposed to induction) may be quite small our transfer experiments do not necessarily exclude this possibility.

## HLA restriction of cell-mediated lysis of influenza virus-infected human cells

MURINE T lymphocytes that mediate the lysis of virus-infected cells show specificity both for the viral cell surface antigens and for the H-2K or D antigens of the major histocompatibility complex<sup>1-8</sup>. The cytotoxic T lymphocytes and the target cell must share H-2K or D products. The experiments reported here demonstrate that there is a similar requirement for partial HLA identity between human cytotoxic lymphocytes and influenza virus-infected target cells.

The viruses used in this study were influenza type A/X31 (A<sub>2</sub>/Hong Kong/68 × A<sub>0</sub>/PR8 (H3N2) and type B/Hong Kong (B/Hong Kong/1/73). H-2 compatibility has been shown to be required for T-lymphocyte-mediated lysis of influenza virus-infected target cells in mice<sup>9-11</sup>. Although there was no cross reaction between type A and B influenza viruses, type A viruses with serologically distinct surface proteins were found to cross react both at the level of secondary induction of cytotoxic cells and in the recognition of infected target cells<sup>7-9</sup>. Consequently, we anticipated that deliberate immunisation of the human volunteers studied would not be necessary, because nearly

all adults have been infected with some influenza viruses of the A group. Similarly, most would have been exposed to viruses of the B type. The individuals studied were therefore asked only to give venous blood samples.

Influenza viruses grown on chick allantoic membranes were used to infect peripheral blood lymphocytes, prepared from heparinised blood by centrifugation on Ficoll-Hypaque. These cells were exposed to virus and after a further 4-h incubation they could be lysed by rabbit antibody to type A influenza virus and complement and therefore expressed viral antigens on their surface. Such infected cells served as stimulator cells for *in vitro* sensitisation or target cells for cell-mediated lysis (CML) (ref. 10). A similarly infected lymphoblastoid cell line (PGF) was also a good target.

Cytotoxic cells could be generated by sensitising peripheral WBC with influenza virus-infected autologous cells, *in vitro*, for 5-8 d at 37 °C. Cell-mediated lysis was then assayed for 5 h on a panel of freshly prepared peripheral blood lymphocytes which were virus-infected and <sup>51</sup>Cr-labelled. These conditions were found to be optimal in preliminary experiments with killer target cell ratios of 40:1 or 50:1. After sensitisation with influenza virus type A/X31 or B/Hong Kong, peripheral blood lymphocytes from J.D. and F.W. killed infected autologous cells, and cytotoxicity was specific for the immunising virus type A or B (Table 1). C.W. cells could be sensitised to A/X31 but not to B/Hong Kong which may indicate that C.W. had not been previously exposed to the B/Hong Kong virus. Otherwise it was apparent that previous exposure to virus *in vivo* had resulted in immunological priming or, less likely, that the cytotoxicity generated *in vitro* represented a primary immune response. Freshly prepared peripheral blood lymphocytes showed no cytotoxic activity towards infected cells and therefore a period of sensitisation *in vitro* was essential. The finding that sensitised J.D. and F.W. cells showed specificity for the virus used for sensitisation only, also confirmed this observation.

The infected target cells used in the cytotoxic assay had been incubated long enough to express viral antigens at the cell surface. Zweerink and Askonas (unpublished data) have shown in the mouse, that this was required before influenza-infected cells could be lysed by cytotoxic T

Table 1 Human cytotoxic lymphocytes show specificity for influenza virus type A or B

Cell donor	Sensitised to influenza type	% <sup>51</sup> Cr release* from target cells infected with		
		A/X31	B/Hong Kong	Uninfected
J.D.	A/X31	36.0	20.2	18.2
	B/Hong Kong	27.3	37.0	18.4
Medium control		21.0	19.5	15.5
F.W.	A/X31	35.5	21.3	15.5
	B/Hong Kong	20.5	35.4	15.5
Medium control		16.0	17.7	15.1
C.W.	A/X31	52.8	13.1	10.3
	B/Hong Kong	29.4	19.4	11.3
Medium control		16.7	9.9	10.5

\* % <sup>51</sup>Cr release = (counts released by target cells/counts released by 2.5% Triton X-100) × 100. <sup>51</sup>Cr-release assay was carried out in triplicate in microtitre II plates<sup>10</sup> using 10<sup>4</sup> virus-infected <sup>51</sup>Cr-labelled peripheral blood lymphocytes and 5 × 10<sup>5</sup> immune cells. Incubation was for 5 h.

Target cells were prepared on the day of the CML assay by infecting peripheral blood lymphocytes with influenza virus type A/X31 or B/Hong Kong (see below). Target cells were radiolabelled by the addition of 100 μCi <sup>51</sup>Cr during the period of infection (90 min), excess <sup>51</sup>Cr was removed by washing cells three times and incubation was continued for 4 h at 10<sup>6</sup> cells ml<sup>-1</sup> in RPMI 1640 medium-10% FCS. J.D. and F.W. were each tested against autologous target cells, and C.W. against HLA compatible target cells. Human peripheral blood lymphocytes were prepared from heparinised venous blood by centrifugation on Ficoll-Hypaque. The cells at the interface were collected and the red blood cells lysed by a 20-min incubation with Tris-buffered 0.75% ammonium chloride at 37 °C. The cells were then washed three times in RPMI 1640 medium (containing 25 mM Hepes buffer, 200 mM glutamine, penicillin and streptomycin). An aliquot of 3 × 10<sup>6</sup> lymphocytes was incubated in 0.2 ml with 100 HA units of influenza virus (A/X31 or B/Hong Kong) at 37 °C for 90 min. After a single wash the cells were incubated for 4 h at 37 °C in 3 ml of RPMI 1640 medium containing 10% foetal calf serum (FCS). They were then washed three times and added to the remaining uninfected peripheral blood mononuclear cells at a ratio of 1:20. The cells were incubated at 10<sup>6</sup> ml<sup>-1</sup> in 4-ml volumes in Bijou bottles (Sterilin) in RPMI 1640-10% FCS for 5-8 d at 37 °C in 5% CO<sub>2</sub> air.

Table 2 Human cytotoxic lymphocytes show specificity for HLA

Cytotoxic cell	% Lysis of influenza A/X31-infected target cells*		
	J.D. (3, 7, W2/2, 7, W2)	F.P. (3, 7, W2/1, 8, -)	F.W. (1, 8, -/1, 8, W3)
C.W. (9, 7, W2/9, 7, W1)	43	30	5
F.W. (1, 8, -/1, 8, W3)	6	16	23

C.W. and F.W. peripheral blood lymphocytes were sensitised to their own lymphocytes infected with influenza type A/X31, and were then tested for cytotoxicity against the influenza type A/X31-infected target cells shown. The HLA types are shown for each individual in the sequence A, B, D/A, B, D.

$$*\% \text{ Lysis} = \frac{^{51}\text{Cr release} - \text{medium control } ^{51}\text{Cr release}}{(^{51}\text{Cr release by Triton X 100}) - (\text{medium control } ^{51}\text{Cr release})} \times 100$$

lymphocytes. Similarly, sensitised human cells failed to lyse autologous cells exposed to ultraviolet-irradiated virus<sup>9</sup>.

Having established that cytotoxic cells show virus specificity the possibility that their activity is HLA-restricted was explored. HLA A, B and C typing was carried out by the standard Terasaki-NIH microcytotoxicity technique. All the individuals studied had also been typed as normal panel blood donors, for B cell (Ia) alloantigens by sera exchanged in the UK regional workshops<sup>11</sup> and Seventh

International workshop. The D locus types thus assigned are those of the UK groups which have been found to correlate with the D specificities defined by mixed lymphocyte typing<sup>11</sup>. The DWI-3 terminology of the Sixth Workshop<sup>12</sup> is therefore retained.

Effector cells specific for influenza type A/X31 were generated from C.W. (HLA 9,7,W2/9,7,W1) and F.W. (HLA 1,8,W3/1,8,-) and these were tested against virus-infected target cells prepared from C.W., F.W. and F.P. (HLA 3,7,W2/1,8,-) (Table 2). Cytotoxic cells from each individual killed the autologous or partially HLA-matched cells but not the HLA-incompatible cells. Each target cell population tested was lysed by at least one effector, which excluded the possibility that a target might be inadequately infected.

This HLA restriction was explored further using C.W. as the effector cell. C.W. lymphocytes sensitised to A/X31 virus were tested against A/X31 virus-infected peripheral blood lymphocytes from 15 individuals, and one lymphoblastoid cell line (P.G.F.). Figure 1 shows the lysis and its correlation with the degree of HLA compatibility between the target cells and C.W. Infected lymphocytes which shared HLA B7 with C.W. were killed—mean percentage lysis  $38.1 \pm 1.9$  s.e.m. Targets that lacked HLA B7 showed minimal lysis; mean  $9.0 \pm 2.6$  s.e.m. This difference was highly significant: (Students'  $t$  10.8  $P < 0.0001$ ). When the target cells shared HLA A9 (W24) or the D locus products DW1 or DW2 only, lysis was not observed.

It is therefore apparent that sharing of HLA B7 with the effector cell was sufficient to allow lysis, whereas sharing of the A or D locus products with C.W. was insufficient. Because it was not feasible to test each target-cell preparation with its autologous sensitised cells, with the exception of F.W. (Table 2), it is theoretically possible that only the HLA B7 positive cells were adequately infected. In previous experiments, however, sensitised cells from eight individuals who were HLA B7 negative lysed autologous influenza A/X31 infected target cells, so that the infection of cells is reproducible.

These findings therefore extend to the human the original observations of Zinkernagel and Doherty<sup>13</sup> that, in the mouse, lymphocyte-mediated lysis of virus-infected cells is restricted by the major histocompatibility complex. This phenomenon is associated with the H-2K and D products which are chemically homologous to HLA A and B antigens<sup>14</sup>. It is therefore appropriate that the restriction involves HLA B in man and that HLA D, which is probably equivalent to the H2 I region, was not involved. It is not clear why in the one pair tested, sharing of the A locus antigen A9 (W24), did not allow lysis. Goulmy *et al.*<sup>15</sup> have found, however, that a human (female) cytotoxic cell population sensitised to the H-Y antigen killed targets that shared an HLA A antigen. It seems, therefore, that HLA B and A are functionally equivalent to H-2K and D. Failure to observe lysis when HLA A9 (W24) was shared might therefore be an effect specific to influenza antigen. Alternatively, the A9 (W24) type might include sub-

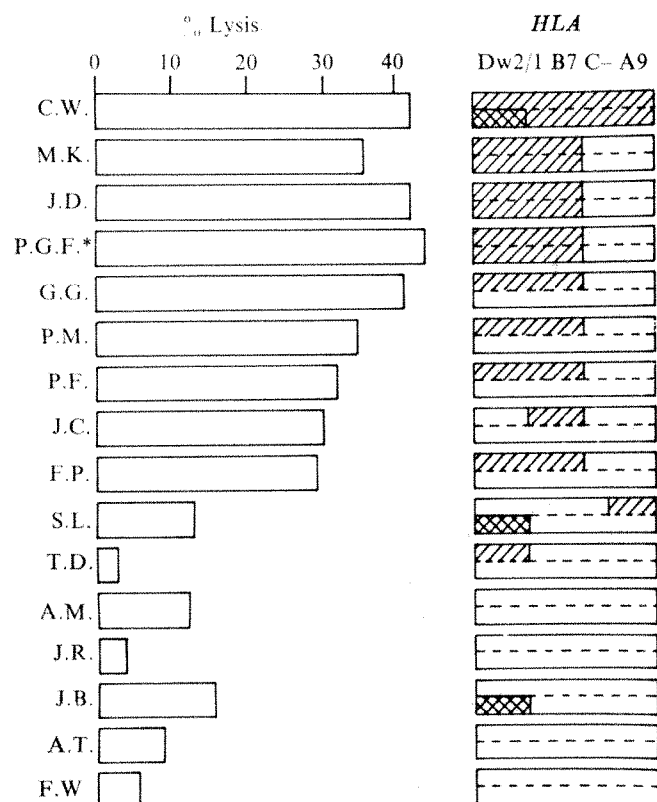

Fig. 1 HLA restriction of cell-mediated lysis of influenza type A/X31-infected cells. C.W. peripheral blood lymphocytes were sensitised to autologous lymphocytes infected with influenza type A/X31, and tested for cytotoxicity against the target cells shown. Results shown as percentage lysis (see legend to Table 2) in the left-hand side of the figure. The degree of HLA compatibility is shown on the right-hand side of the diagram. Sharing of HLA DW2, or B7, C-, A9 is represented by diagonal hatching either as one haplotype (top half only) or two haplotype compatibility (both halves). Sharing of HLA DW1 is shown by cross-hatching. The HLA A, B, D types of the target cells were C.W.: (autologous target), 9(W24), 7, W2/9 (W24), 7, W1; M.K.: 3, 7, W2/3, 7, W2; J.D.: 3, 7, W2/2, 7W2; \*P.G.F.: 3, 7, W2/3, 7, W2; G.G.: 2, 3, 7, W14, -, W2; F.P.: 3, 7, W2/1, 8, -; S.L.: 9(W24), W30, 13, W15, W1, -; T.D.: 2, 2, 12, W40, 2, -; A.M.: 2, 21, -/W32, W40, -; J.R.: 2, 2, 12, 27, -, -; J.B.: W30, W32, W15, -, W3, W1; A.T.: 2, 11, W40, W22, -, -; F.W.: 1, 8, W3/1, 8, -.

\*P.G.F. was a lymphoblastoid cell line, donated by Professor W. F. Bodmer.

groups that, although serologically related, might not behave as an identical pair in target-cell recognition. This would be analogous to the failure of H-2<sup>b</sup> mouse cytotoxic cells to recognise target cells that share the mutant H-2<sup>ba</sup> K antigen<sup>16</sup>. Indeed, if such mutants are common in the human population, apparent HLA homozygotes that are really wild × mutant HLA heterozygotes would lyse a larger selection of target cells than true homozygotes.

The HLA types of the individuals used as cytotoxic cell donors show linkage disequilibrium. The haplotypes A1-B8-DW3 and B7-DW2 occur in Caucasian populations at frequencies that are much greater than would be expected from the gene frequencies of the individual antigens<sup>17</sup>. This means that, if the recognition of target cells involves genes closely linked to HLA-B, these are likely to be the same when killer and target cells share an HLA haplotype. This is another possible explanation for the lack of killing when HLA A9 (W24), which is not in linkage disequilibrium with B7, was shared.

This finding that there is HLA restriction of cell-mediated lysis of influenza virus-infected cells is in accord with data in the mouse showing that for influenza<sup>3-8</sup> and other viruses<sup>1-4</sup> there is H2 restriction. It contrasts with reports that human cytotoxic T lymphocytes showed no HLA restriction in the lysis of Epstein-Barr virus<sup>17</sup> or measles virus<sup>18</sup>-infected cell lines.

We thank Dr J. J. Skehel for gifts of influenza viruses A/X31 and B/Hong Kong and Professor P. J. Morris for helpful advice and encouragement. This work was supported by a grant from the Wellcome Trust, and an MRC programme grant to Professor P. J. Morris. A. J. McM is a Wellcome Senior Clinical Research Fellow. H.J.Z. is the recipient of a USPHS Career Development Award and a fellowship of the John Simon Guggenheim Memorial Foundation.

## Human cell-mediated cytotoxicity against modified target cells is restricted by HLA

T-CELL-mediated lysis of virus-infected target cells in mice is restricted by the H-2D and H-2K antigens of the major histocompatibility complex (MHC) in the sense that the cytotoxic T cells are only active against virus-infected target cells sharing H-2D and/or H-2K antigens with the animal in which the killer cells have been raised<sup>1</sup>. These findings led to a better understanding of the way in which the MHC regulates certain functions of the immune system<sup>2</sup>, and they have been amply confirmed by further studies in inbred strains of mice and guinea pig which have indicated that restriction by antigens of the MHC is a general phenomenon in the T-cell-mediated immune response<sup>3</sup> in these species. Evidence for MHC restriction of the immune response in man, however, was lacking until it was shown that a female patient who had rejected a bone marrow graft from her HLA-identical brother, had cytotoxic cells in her blood, and that the activity of these cells was restricted to male target cells which had the HLA-A2 antigen in common with herself<sup>4</sup>. We show here in a more general way, that the cell-mediated cytotoxicity which can be raised in humans against 'altered self' is restricted by the HLA-A, B and C antigens.

It has been shown that peripheral lymphocytes from subjects who have been sensitised by skin painting with DNCB respond with proliferation when cocultured *in vitro* with autologous irradiated and dinitrofluorobenzene (DNFB)-conjugated lymphocytes<sup>5</sup>. We have investigated the generation of cytotoxic cells in such cultures. Individuals were sensitised to DNCB following their informed consent, as a part of a clinical study of the immune response in a group of patients suffering from various allergic disorders, primarily asthma bronchiale. Within this group, subjects with minor disease activity gave permission to use some of their blood samples for a study not directly related to their disorder. A total of 27 subjects were examined. All showed contact sensitivity against DNCB. This hypersensitivity followed either the application of 2,000 µg DNCB dissolved in 50 µl acetone on the volar surface of each forearm, or subcutaneous injection of 25 × 10<sup>6</sup> DNFB-treated autologous lymphocytes. All subjects were investigated 2-5 weeks after the sensitisation by the method described in the legend to Table 1. Briefly, mononuclear blood cells were mixed with an equal amount of DNFB-treated autologous mononuclear cells and cultured for 8 d *in vitro*. The cytotoxic capacity of these *in vitro* restimulated cells was then investigated on <sup>51</sup>Cr-labelled, DNFB-treated autologous PHA-stimulated lymphocytes, revealing that 14 of the 27 individuals produced cytotoxic cells against autologous DNFB-coupled target cells. Eight were strongly positive and of these, one could not be retested, and two had lost most of the reactivity when retested 2-3 weeks after the first investigation. The results of retesting the remaining five individuals against selected panels of unrelated allogeneic lymphocytes are given in Table 1. The panels were selected according to the HLA types of the sensitised individuals and represented various degrees of HLA disparity. Freshly explanted lymphocytes from the sensitised subjects had no direct cytotoxic activity, and we have not succeeded in generating DNFB-directed cytotoxic cells *in vitro* with lymphocytes from non-immunised subjects.

It is obvious that cytotoxic activity is directed only against DNFB-coupled target cells. Of these, only autologous targets or targets sharing one or more HLA-A,B antigens with the cytotoxic effector cell were lysed, whereas there was no or (in two cases) only weak activity against totally HLA-A,B different target cells. These results show

Mononuclear cells were isolated by Ficoll-hypaque flotation from defibrinated venous blood. Responder cells from the sensitised donors were resuspended to a concentration of  $1.5 \times 10^6$  cells  $\text{ml}^{-1}$  in RPMI-1640 supplemented with antibiotics, glutamine and 15% pooled heat-inactivated human serum ('Ned. H'). Stimulator cells were resuspended in RPMI-1640 ( $\approx 5 \times 10^6$  cells  $\text{ml}^{-1}$ ) and to each ml of suspension was added 0.1  $\mu\text{l}$  of a 2% solution of DNFB in acetone, followed by incubation at room temperature in the dark for 30 min. The DNFB-treated cells were washed twice, resuspended in Med. H at a concentration of  $1.5 \times 10^6$  cells  $\text{ml}^{-1}$  and irradiated with 2,300 rad. Equal amounts of responder and stimulator cell suspensions were mixed and incubated in flat-bottomed tubes in 5-ml portions for 8 d at 37 °C in a humidified atmosphere with 5%  $\text{CO}_2$ . The portions were then pooled, the cells washed once, and resuspended in fresh Med. H at a concentration of  $5 \times 10^6$  Trypan-blue excluding cells per ml (effector cells). Target cells were prepared by incubating  $2 \times 10^6$  phytohaemagglutinin (PHA)-stimulated mononuclear cells (1  $\mu\text{l}$  PHA-P (Wellcome) per ml suspension of  $1 \times 10^6$  cells  $\text{ml}^{-1}$  in Med. H incubated for 3 d) with 250  $\mu\text{Ci}$   $\text{Na}_2^{51}\text{CrO}_4$  in 0.5 ml RPMI for 45 min at 37 °C. Some of the target cells were coupled with DNFB as described above, but five times as much DNFB was used per ml of cell suspension. The washed target cells were resuspended at a concentration of  $1 \times 10^5$  cells  $\text{ml}^{-1}$  in Med. H. 200  $\mu\text{l}$  of the effector cell suspension and 100  $\mu\text{l}$  of the target cell suspension were mixed in roundbottomed microtest tubes and incubated for 5 h at 37 °C. The test tubes were centrifuged and radioactivity in the supernatant and cell pellet was counted in a gammacounter. Target cells were incubated in parallel in medium alone and the  $^{51}\text{Cr}$  releases were calculated as percentage of  $^{51}\text{Cr}$  released relative to the amount incorporated in the target cells at the start of the experiment. Specific  $^{51}\text{Cr}$ -release was expressed as (release in mixtures with effector cells) - (release in medium alone). The releases in medium (control) were between 7% and 15%. Experiments were carried out in duplicate or triplicate, and s.e.m.s. were between 1 and 3%. A reaction was considered positive when the specific release exceeded 5%.

\* Donors KR, JR and VH were sensitised by injection of autologous DNFB-treated cells.

† Donors OT and MC were sensitised by the application of DNCB on the skin.

TF, Technical failure.

Antigens in common between effector and target cells and italicised. Two cases of target cell killing not restricted by HLA-A, B, C are also italicised.

that the phenomenon of MHC-restricted cell-mediated cytotoxicity also applies to man. We have no unequivocal proof that the cytotoxicity is mediated by T cells. However, more than 90% of the viable cells in the washed effector cell suspension formed rosettes with sheep red blood cells (SRBC). In donor MC an SRBC-rosetted effector cell suspension was separated by Ficoll-Hypaque density flotation. Too few cells were found in the interphase (non-rosetted cells) to be tested for cytotoxic activity. The sedimented SRBC-rosetted cells were collected and after lysis of the SRBC by fresh human AB serum, the cells were tested for cytotoxic activity. These cells had strong DNFB-directed cytotoxic activity (Table 1).

In the three cases where the effector cell donor was HLA-A2, most of the reactivity could be explained by preferential restriction by A2 alone. In fact, the experiments involving this antigen gave the highest specific releases. This might suggest that there is a hierarchy of antigenicity among the antigenic determinants produced by DNFB treatment, in the sense that one HLA antigen conjunction, when available, is preferred to the other possible conjunctions. Preferential restriction by only some of the MHC antigens available has been seen in several mice<sup>6-8</sup>, and might be

caused either by properties of the MHC antigens themselves or by immune response genes. Whereas the first possibility seems most likely in the present case (particularly the A2 antigen may have a unique role in cytotoxicity), evidence has been presented which evokes Ir genes in the mice systems<sup>6,7</sup>. Only some of the sensitised donors generated DNFB-directed cytotoxicity detectable by our *in vitro* system. The successful cases could be fortuitous results of a complex multifactorial interaction, but it is possible that a major factor of genetically determined immune responsiveness may have a role. Further studies are needed to clarify these questions, which have obvious implications for our understanding of the maintenance of MHC polymorphism.

The two cases of non HLA-A, B, C restricted target cell killing (if not technical artefacts) could be explained by (1) cytotoxicity exclusively directed against DNFB; (2) DNFB treatment may make target cells liable to killing by cytotoxic effector cells of any specificity; (3) cytotoxicity could be directed against DNFB-'modified' common cell-surface components other than the known HLA-A,B,C antigens; and (4) cross reactions between DNFB-'modified' HLA-A, B, C antigens which are not necessarily revealed by

the known serological cross reactions between HLA antigens. The first two possibilities seem unlikely in view of the many negative reactions with DNFB-treated target cells shown in Table 1.

The DNFB-directed cytotoxic activity could be induced *in vitro* only in lymphocytes from sensitised donors, whereas alloaggressive cytotoxicity is easily induced after primary sensitisation *in vitro*<sup>9</sup>. This presumably reflects the phenomenon emphasised by Simonsen<sup>10</sup>, that the number of antigen-sensitive cells primarily reactive against allotypic MHC-antigens in an unsensitised organism is much greater than that of cells primarily reactive against other antigens.

The main purpose of the present study was to investigate whether the phenomenon of MHC-restricted cell-mediated cytotoxicity applies also in man. Having shown that this is the case, work is now in progress to help resolve some of the new questions raised. Moreover, it seems likely that studies of contact hypersensitivity diseases with modifications of the present technique could elucidate the pathogenesis in these disorders.

## Conventional calcium channel mediates asynchronous acetylcholine release by motor nerve impulses

STIMULATION of the motor nerve, in addition to producing the synchronous, impulsive release of acetylcholine (ACh) that is recorded electrophysiologically as the endplate potential (e.p.p.)<sup>1</sup>, also elicits a delayed, asynchronous discharge of ACh quanta that appears as increases in miniature endplate potential (m.e.p.p.) frequencies<sup>2–4</sup>. The synchronous release of ACh is mediated by the movement of  $\text{Ca}^{2+}$  through specific conductance channels activated by depolarisation of the motor nerve ending (for reviews see refs 1, 5 and 6). Although asynchronous release is dependent in some fashion on extracellular ( $\text{Ca}^{2+}$ ) (ref. 4) there seems to be a controversy as to the precise nature of the ionic pathway responsible for this dependence. For example, although it has been suggested that asynchronous evoked release is mediated by residual  $\text{Ca}^{2+}$  that enters through the traditional  $\text{Ca}^{2+}$  conductance pathway<sup>3</sup>, results with  $\text{Mg}^{2+}$  have suggested the contrary<sup>4</sup>. Specifically, it has been shown that  $\text{Mg}^{2+}$ , rather than antagonising the asynchronous release of ACh in  $\text{Ca}^{2+}$  solutions, (as would be expected if  $\text{Ca}^{2+}$  moved through the same conductance pathway for both forms of release<sup>7–10</sup>), actually enhanced the asynchronous discharge of ACh quanta<sup>4</sup>. The present study investi-

gated the effects of the conventional  $\text{Ca}^{2+}$  antagonists,  $\text{Co}^{2+}$  and  $\text{Mg}^{2+}$ , on the asynchronous evoked release of ACh. The results demonstrate that after brief, repetitive stimulation, both ions competitively antagonise asynchronous ACh release in a manner similar to their respective antagonism of synchronous release<sup>7,10</sup>. We conclude that  $\text{Ca}^{2+}$  supports both dispersed and synchronous ACh release through the same conductance pathway.

Experiments were carried out using isolated nerve-cutaneous pectoris preparations of the frog, which were bathed in normal Ringer solution of the following composition (mM): NaCl 115, KCl 2,  $\text{NaHCO}_3$  2 and  $\text{CaCl}_2$  1.8 (pH 6.8–7.2). Neostigmine methylsulphate ( $1 \mu\text{g ml}^{-1}$ ) was added to all solutions to increase the size of the m.e.p.p.s. In most experiments, after an initial wash in normal Ringer, 400 mM glycerol was added to the normal Ringer (glycerol Ringer) and the preparation bathed in glycerol Ringer for 1 h. When the preparation is returned to normal Ringer after glycerol treatment, the transverse tubule system of the muscle ruptures<sup>11</sup>. This procedure allowed evoked ACh release to be studied in a full range of  $\text{Ca}^{2+}$  concentrations without fear of dislodging the recording electrode mechanically from the interior of the muscle fibre. Intracellular recordings were obtained from endplate regions using microelectrodes filled with 3 M KCl (resistances ranging from 10–25 MΩ). The signal from the microelectrode was fed into a conventional preamplifier (W. P. Instruments) and then in parallel into an oscilloscope (Tektronix model 5103N) and a pen recorder (Brush-Gould model 220). M.e.p.p. frequencies were measured from pen records. In the presence of  $\text{Ca}^{2+}$ , stimuli were delivered to the motor nerve at a frequency of 20 Hz (for 0.5–5 s) and the evoked

**Fig. 1** Competitive antagonism of  $\text{Ca}^{2+}$ -mediated asynchronous release by  $\text{Co}^{2+}$ . Stimuli were delivered at 20 Hz for 800 ms ( $\blacktriangle$ ). The preparation was pretreated with glycerol Ringer. Evoked m.e.p.p. frequencies were determined during the 4-s period immediately after nerve stimulation. All figures are photographs of pen recorder traces. *a*, Normal (1.8 mM  $\text{Ca}^{2+}$ ) Ringer. During nerve stimulation large e.p.p.s are produced (which are superimposed on the underlying depolarisation produced by residual ACh). After nerve stimulation, a residual discharge of individual m.e.p.p.s occurs. For *a*, *b* and *c*, resting m.e.p.p. frequency was  $2 \text{ s}^{-1}$ . Constancy of resting m.e.p.p. frequency was maintained by adding appropriate amounts of sucrose to the Ringer solution. In *a* the m.e.p.p. frequency after stimulation was  $4.4 \text{ s}^{-1}$ ; *b*, 1.8 mM  $\text{Ca}^{2+} + 0.5 \text{ mM Co}^{2+}$  Ringer, note the antagonism of both e.p.p. amplitude and evoked m.e.p.p. discharge by  $\text{Co}^{2+}$ . M.e.p.p. frequency after stimulation  $2 \text{ s}^{-1}$ ; *c*, 7.0 mM  $\text{Ca}^{2+} + 0.5 \text{ mM Co}^{2+}$  note partial surmounting of  $\text{Co}^{2+}$ -induced depression by increasing the  $[\text{Ca}^{2+}]$ . M.e.p.p. frequency after stimulation  $3.1 \text{ s}^{-1}$ . In this experiment, 9.0 mM  $\text{Ca}^{2+} + 0.5 \text{ mM Co}^{2+}$  Ringer produced a matching evoked m.e.p.p. discharge to that produced in normal Ringer.

**Fig. 2** Antagonism of  $\text{Ca}^{2+}$ -mediated, asynchronous release by  $\text{Mg}^{2+}$ . The preparation was pretreated with glycerol Ringer. Stimulation ( $\blacktriangle$ ) was delivered at a frequency of 20 Hz for 1 s. *a*, 1.8 mM  $\text{Ca}^{2+}$  Ringer resting m.e.p.p. frequency,  $2.4 \text{ s}^{-1}$ , evoked m.e.p.p. frequency,  $5.9 \text{ s}^{-1}$ ; *b*, 1.8 mM  $\text{Ca}^{2+}$  + 10 mM  $\text{Mg}^{2+}$  Ringer, resting m.e.p.p. frequency,  $3.9 \text{ s}^{-1}$ , evoked m.e.p.p. frequency,  $4.1 \text{ s}^{-1}$ , note the antagonism of evoked m.e.p.p.s by  $\text{Mg}^{2+}$ ; *c*, 6.25 mM  $\text{Ca}^{2+}$  + 10 mM  $\text{Mg}^{2+}$  Ringer, resting m.e.p.p. frequency,  $5.8 \text{ s}^{-1}$  evoked m.e.p.p., frequency  $11.6 \text{ s}^{-1}$ . Antagonism was surmounted by increasing the  $[\text{Ca}^{2+}]$ . For further explanation, see Fig. 1.

m.e.p.p. frequencies measured for the 4-s period after stimulation. During stimulation, a large depolarisation of the postsynaptic membrane (produced by inadequate removal of the enormous quantities of ACh poured into the synaptic cleft<sup>12</sup>) drove the recorder pen off the scale (see, for example, Figs 1 and 2). To ensure faithful counting of m.e.p.p. frequencies during repolarisation after stimulation, either (1), one output of the recorder was differentially biased with respect to the other, so that when the pen had moved off the scale on the lower part of one channel, it appeared on the scale at the upper part of the other channel or (2), the output terminal of the a.c.-coupled oscilloscope amplifier was fed directly into the recorder.

Figure 1 illustrates a typical experimental result from a preparation pretreated with glycerol Ringer. In Fig. 1*a*, repetitive nerve stimulation in normal Ringer (1.8 mM  $\text{Ca}^{2+}$ ) produced e.p.p.s superimposed on a depolarising membrane potential and a residual discharge of m.e.p.p.s after the stimulation period. In this trace, the m.e.p.p. frequency increased from a resting level of  $2 \text{ s}^{-1}$  to approximately  $4.5 \text{ s}^{-1}$  after stimulation. The addition of 0.5 mM  $\text{Co}^{2+}$  to normal Ringer (Fig. 1*b*) depressed the e.p.p. amplitude and fully antagonised the evoked discharge of m.e.p.p.s. Increasing the extracellular  $\text{Ca}^{2+}$  to 7.0 mM in the presence of  $\text{Co}^{2+}$  (Fig. 1*c*) enabled the antagonism of both the e.p.p. amplitude and evoked m.e.p.p. frequency to be overcome. In this experiment, a concentration of 9.0 mM  $\text{Ca}^{2+}$  was necessary to produce an evoked discharge of m.e.p.p.s that matched the control response (Fig. 1*a*). Note that in this experiment, changes in the resting m.e.p.p. frequencies (as a consequence of tonicity changes of the various Ringer solutions) were prevented by the addition of appropriate amounts of sucrose to the Ringer. In several experiments it was possible to construct a log dose-response curve for  $\text{Ca}^{2+}$ -evoked m.e.p.p.s and to observe a parallel shift in this curve in the presence of  $\text{Co}^{2+}$ . This suggests that  $\text{Co}^{2+}$  acts as a competitive antagonist of asynchronous

release<sup>8,12</sup>, much as it does for synchronous release<sup>10,13</sup>. The equilibrium dissociation constant ( $K_d$ ) for  $\text{Co}^{2+}$  as a competitive antagonist of asynchronous release can be calculated as follows<sup>8,13</sup>

$$K_d = ((\text{Ca}_2/\text{Ca}_1) - 1)^{-1} [\text{antagonist}] \quad (1)$$

where  $\text{Ca}_1$  is the  $[\text{Ca}^{2+}]$  that produces a certain evoked discharge of m.e.p.p.s and  $\text{Ca}_2$  is the  $[\text{Ca}^{2+}]$  that produces an identical evoked discharge of m.e.p.p.s in the presence of the antagonist. In four experiments in which the resting m.e.p.p. frequency remained essentially unchanged, the  $K_d$  for  $\text{Co}^{2+}$  ranged from 0.10 to 0.15 mM with a mean for all experiments of 0.13 mM. This value compares favourably with the reported values of  $\text{Co}^{2+}$  as an antagonist of synchronous release (0.07 mM (ref. 10), 0.18 mM (ref. 14)) suggesting that both forms of release may share a common conductance pathway.

Further evidence in support of this contention was provided by experiments using  $\text{Mg}^{2+}$ . In the experiment shown in Fig. 2, stimulation in normal Ringer after glycerol treatment produced a large increase in m.e.p.p. frequency from a resting level of  $2.4 \text{ s}^{-1}$  to  $6 \text{ s}^{-1}$  after stimulation. Addition of 10 mM  $\text{Mg}^{2+}$ , although causing a slight increase in resting frequency to  $3.9 \text{ s}^{-1}$  (presumably because of increased tonicity of the Ringer), fully antagonised the evoked discharge of m.e.p.p.s. Increasing the  $[\text{Ca}^{2+}]$  to 6.25 mM,

**Fig. 3** Slow increases in m.e.p.p. frequency evoked by prolonged (40 s) stimulation at 50 Hz in 10 mM  $\text{Mg}^{2+}$  Ringer. Upper trace, control m.e.p.p. frequency,  $0.5 \text{ s}^{-1}$ ; Middle traces, m.e.p.p. frequencies at indicated times after starting stimulation. Spikes on baseline indicates stimulus artefacts. Lowest trace, m.e.p.p. frequency immediately after stimulation,  $6 \text{ s}^{-1}$ . Note that a discernable increase in m.e.p.p. frequency begins only after 18 s of stimulation. Similar records were produced in the presence of 1 mM  $\text{Co}^{2+}$ .

although further increasing the resting frequency, overcame the antagonism of evoked m.e.p.s by  $Mg^{2+}$ . Experiments where the change in resting m.e.p.p. frequency was prevented by adding sucrose to the Ringer solutions were used to calculate the  $K_d$  for  $Mg^{2+}$  (equation 1). Indeed, the mean  $K_d$  for  $Mg^{2+}$  is  $4.6 \pm 0.2$  mM (mean  $\pm$  s.e.,  $n=4$ ) as an antagonist of asynchronous release is similar to the values for  $Mg^{2+}$  as an antagonist of synchronous release (4.0 mM, 3.0 mM, 4.4 mM: refs 8–10 respectively).

These results, demonstrating that  $Mg^{2+}$  antagonises the asynchronous  $Ca^{2+}$ -dependent discharge of m.e.p.s seem to be at variance with those suggesting that  $Mg^{2+}$  enhances the asynchronous release of ACh. It is possible that the ability of  $Mg^{2+}$  to activate asynchronous evoked release may appear only after prolonged, high frequency stimulation. Figure 3 illustrates a representative experiment which suggests that this is the case. Note that it is only after 18 s of high frequency (50 Hz) stimulation in 10 mM  $Mg^{2+}$  Ringer that discernable increases in m.e.p.p. frequency were observed. This is in contrast to the results shown in Figs 1 and 2, where stimuli were delivered at a frequency of 20 Hz for a brief period ( $\leq 1$  s). In the experiment of Fig. 3 m.e.p.p. frequencies were elevated from the control level of  $0.5 s^{-1}$  (upper trace) to  $6 s^{-1}$  immediately after 40 s of stimulation (lowest trace). A concentration of  $Co^{2+}$  as high as 1 mM did not alter either the time course or the absolute increase in m.e.p.p. frequency produced by stimulation in 10 mM  $Mg^{2+}$  Ringer. It thus seems that  $Ca^{2+}$  and  $Mg^{2+}$  support asynchronous release through different ionic conductance channels<sup>4,15</sup>.

In conclusion, the results suggest that the  $Ca^{2+}$ -dependent asynchronous release of ACh by nerve stimulation is mediated by the same conductance pathway as synchronous release. It is interesting that  $Ba^{2+}$  (which does not support synchronous release<sup>16</sup>) and  $Sr^{2+}$  (which can only poorly support synchronous release<sup>17</sup>) both produce large discharges of m.e.p.s after brief repetitive nerve stimulation. In contrast to  $Mg^{2+}$ , however, both  $Ba^{2+}$  and  $Sr^{2+}$  support asynchronous release through the same conductance pathway normally traversed by  $Ca^{2+}$  in mediating the synchronous and asynchronous discharge of ACh quanta (ref. 18 and our work in preparation).

## Role of prostaglandin-mediated vasodilatation in inflammation

INFLAMMATORY reactions are characterised by hyperaemia, and exudation of plasma resulting in tissue swelling. Putative mediators of inflammation have usually been evaluated according to their ability to mimic inflammatory reactions<sup>1</sup>. Although prostaglandins were identified in inflammatory exudates<sup>2</sup>, and prostaglandin synthesis *in vitro* was shown to be inhibited by non-steroid anti-inflammatory compounds<sup>3–5</sup>, prostaglandins (unlike histamine and bradykinin) were found to be poor at eliciting plasma exudation when injected into guinea pig<sup>6–7</sup> or rabbit skin<sup>8</sup>. But, the finding that exogenous prostaglandins (notably of the E-type) potentiate plasma exudation produced by other mediators<sup>7–11</sup> suggested that this may be the role of prostaglandins in inflammation. An alternative view has been proposed by Kuehl *et al.*<sup>12</sup>, who consider that since E and F prostaglandins fail fully to mimic inflammatory reactions, other products of arachidonic acid should be considered as mediators. They suggest that the unstable prostaglandin endoperoxide,  $PGG_2$ , or a non-prostaglandin product of it (a free radical could be the important mediator. We have re-examined the mode of action of prostaglandins in inflammation by measuring both increased blood flow and plasma exudation. The results presented here

**Fig. 1.** Plasma exudation (upper) and local blood flow changes (lower) measured simultaneously in rabbit skin in response to various agents. In each experiment a New Zealand White rabbit was given an intravenous injection (approximately 15  $\mu$ Ci per kg body weight) of  $^{131}I$ -labelled human serum albumin and a short-acting anaesthetic, methohexitone sodium (approximately 10 mg per kg). Intradermal injections (0.1 ml) of inflammatory agents mixed with  $^{133}Xe$  (5–10  $\mu$ Ci per injection) were then given into the clipped back skin in random-block order. After 20 min the animal was killed, skinned, and a 16-mm diameter punch was used to remove injection areas. Samples of skin, blood, and injection fluid were counted in an automatic  $\gamma$ -counter. Plasma volumes of skin samples ( $\mu$ l per sample) and local blood changes (% increase above controls) were computed as previously described<sup>16</sup>. *a*, Comparison of the responses produced by bradykinin (Bk) and  $PGE_2$  at the doses shown. Bradykinin produced exudation with little blood flow increase. Conversely,  $PGE_2$  produced little exudation but a large increase in blood flow. *b*, Effect of adding increasing doses of  $PGE_2$  to a fixed dose of histamine (H, 2.5  $\mu$ g) resulting in an increase in blood flow and a potentiation of exudation. In both *a* and *b* the shaded areas denote the amount of exudation produced above that produced by the permeability-increasing agent alone; dashed lines represent saline control level for both plasma volume and blood flow; single dash represents saline injection. Values are means  $\pm$  s.e.m.,  $n = 6$ .

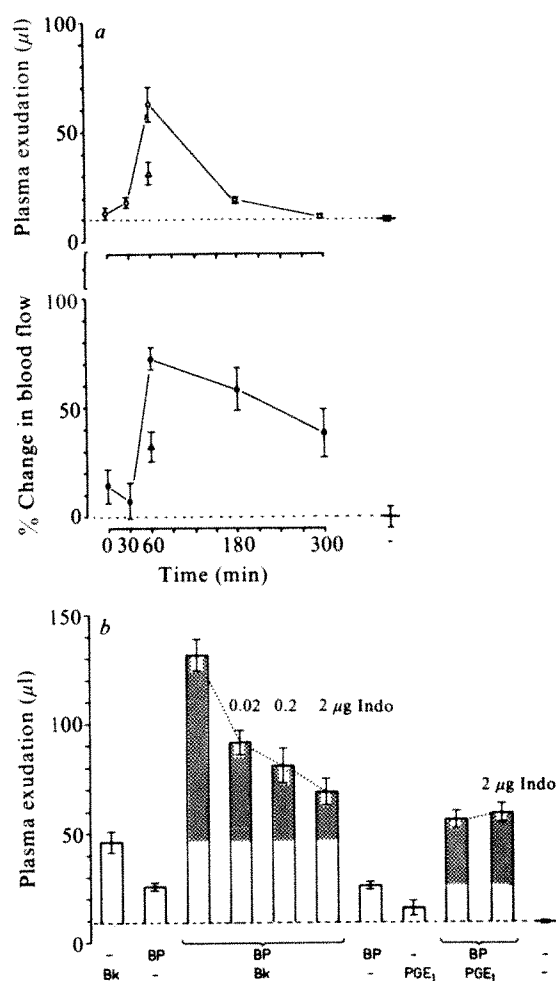

**Fig. 2** Four experiments showing potentiation of exudation responses to bradykinin (Bk, 500 ng) by: PGE<sub>1</sub> (10 ng); adenosine (A, 100  $\mu\text{g}$ ); arachidonate (AA, 1  $\mu\text{g}$ ); and PGG<sub>2</sub> (100 ng). Addition of 1  $\mu\text{g}$  indomethacin (Indo) suppressed only the potentiation produced by arachidonate. Incubation of PGG<sub>2</sub> in saline at 37 °C for 10 min (PGG<sub>2</sub>\*) did not reduce its potentiating activity. Potentiation produced by the same dose (100 ng) of PGE<sub>2</sub> is shown for comparison. Values are means  $\pm$  s.e.m.,  $n = 6$ .

suggest that the mediation of vasodilatation and increased vascular permeability should be considered separately. Prostaglandins (notably the E-type<sup>13,14</sup>) mediate vasodilatation (although they may have some additional mast cell degranulating activity in the rat<sup>15</sup>). It is this vasodilatation which is responsible for the potentiation of the exudation produced by other mediators. Our observations provide a new hypothesis for the microvascular mechanisms involved in the action of non-steroid anti-inflammatory compounds.

Plasma exudation and local blood flow changes were measured in rabbit skin using the accumulation of intravenously-injected <sup>131</sup>I-albumin and wash-out of intradermally-injected <sup>133</sup>Xe, as previously described<sup>16</sup>.

Figure 1a shows that intradermal injection of E-type prostaglandin produced a large increase in local blood flow with little plasma exudation (often undetectable). Bradykinin (and histamine at larger doses), on the other hand, increased vascular permeability resulting in plasma exudation (for 10–15 min following injection<sup>17</sup>), but they were far less potent at increasing blood flow. An example of the exudation-potentiating activity of prostaglandins is shown in Fig. 1b, which demonstrates that addition of increasing doses of PGE<sub>2</sub> to a fixed dose of histamine resulted in increasing blood flow and an enhancement of exudation. We have previously reported<sup>8</sup> that exudation potentiation correlates with the vasodilator activity of prostaglandins, and a similar relationship has been observed using other techniques<sup>18</sup>. First, the rank order of different prostaglandins was the same for exudation-potentiating potency as for blood flow-increasing potency<sup>8</sup>, that is, PGE > PGA > PGF > PGD. Second, local injection of substances, other than prostaglandins, which increased skin blood flow, for example isoprenaline, ADP, and adenosine (see Fig. 2b), also had exudation-potentiating activity<sup>8</sup>. Conversely, substances which reduced skin blood flow, for example noradrenaline and angiotensin II, reduced exudation and blood flow in parallel<sup>8</sup>. From these results we conclude that prostaglandins increase histamine- and bradykinin-induced plasma exudation not by increasing vascular permeability, but by increasing vasodilatation. The exact mechanism of this is not clear, but extrapolation from observations on the transport of

**Fig. 3** a, Time course of exudation (○), and blood flow changes (●) produced by intradermal injection of killed *B. pertussis* vaccine ( $2.5 \times 10^8$  organisms per site) into an unsensitised rabbit. Responses varied between animals; for example exudation, mean  $23.1 \pm 3.0 \mu\text{l}$ , range 3.6–71.9  $\mu\text{l}$ ,  $n = 32$  rabbits (six measurements per animal). Abscissa is time between *B. pertussis* injections and following injections of isotopes. Exudation and blood flow were measured over a further 20 min period. Indomethacin (1  $\mu\text{g}$ ), mixed with the vaccine before injection reduced both blood flow increase (▲) and, therefore (according to the hypothesis), exudation (Δ). b, Enhanced exudation, at the peak of the response to intradermal *B. pertussis* injection, produced by a further injection of either bradykinin or PGE<sub>1</sub>. Potentiation of exudation produced by a first injection (scale top line) of *B. pertussis* (BP) and a second injection (lower line), 60 min later, of bradykinin (500 ng). Exudation was measured over the following 30 min. This effect was suppressed by locally-injected indomethacin (dose equally divided between first and second injections). The potentiation produced by a first injection of *B. pertussis* and a second injection of PGE<sub>1</sub> (500 ng) was unaffected by locally-injected indomethacin. Values are means  $\pm$  s.e.m.,  $n = 6$ .

macromolecules from blood to lymph in dog paw following thermal injury<sup>19</sup>, suggest that exudation potentiation results from an increase in total vessel wall exchange area in the dilated vascular bed.

Figure 2 shows potentiation of bradykinin-induced exudation by PGE<sub>1</sub>, adenosine, arachidonate<sup>20</sup>, and PGG<sub>2</sub>. Adenosine is included as an example of a non-prostaglandin vasodilator. All four agents produced little exudation when injected alone. Potentiation produced by PGE<sub>1</sub> (and PGE<sub>2</sub>, not shown), adenosine, and PGG<sub>2</sub>, was unaffected by locally-injected indomethacin; whereas that produced by arachidonate, the PGE<sub>2</sub> precursor (and similarly dihomo- $\gamma$ -linolenate, the PGE<sub>1</sub> precursor) was suppressed. These results are consistent with the proposition that indomethacin suppresses inflammatory dilatation, and as a consequence inflammatory oedema, by preventing the production of a vasodilator substance via the cyclo-oxygenase pathway. Although the importance of the unstable prostaglandin endoperoxide, PGG<sub>2</sub>, has been emphasised<sup>12</sup>, it is interesting to

note that  $\text{PGG}_2$  injected alone produced little exudation. Furthermore, the exudation-potentiating potency of  $\text{PGG}_2$  was less than that of  $\text{PGE}_2$  and was unaffected by incubation in saline for 10 min at  $37^\circ\text{C}$  (which would leave little  $\text{PGG}_2$  unchanged). This would suggest that the observed activity of  $\text{PGG}_2$  *in vivo* was due to one of its products,  $\text{PGE}_2$ . Indeed, although injection of  $\text{PGG}_2$  produced a net increase in blood flow over the period measured (20 min), other evidence based on the time course of  $^{133}\text{Xe}$  clearance<sup>21</sup> would suggest that the endoperoxides themselves may have vasoconstrictor activity.

The results obtained using exogenous agents suggest that inflammation may involve the separate production of permeability-increasing mediators and vasodilator mediators. This is supported by results from experiments using intradermal injections of killed *Bordetella pertussis* vaccine in unsensitized rabbits. Other materials produced similar results, for example Zymosan, glycogen and carrageenan. Intradermal injection of *B. pertussis* resulted in exudation and increased blood flow with a peak at 60–80 min (Fig. 3a). Indomethacin suppressed both exudation and increased blood flow (Fig. 3a). The presence of an endogenous vasodilator (exudation-potentiating) mediator was established by injecting bradykinin at the peak of the response, 60 min after *B. pertussis* injection. The exudation response to bradykinin was potentiated (Fig. 3b) and this effect was inhibited by locally-injected indomethacin. The presence of an endogenous permeability-increasing mediator (unlikely to be either histamine or a kinin; T.J.W., unpublished observations) was established by injection of  $\text{PGE}_1$  60 min after *B. pertussis* injection.  $\text{PGE}_1$  also produced potentiation (Fig. 3b) but this effect was unaffected by indomethacin. Thus, indomethacin inhibited the production of the vasodilator (exudation-potentiating) mediator(s), and not the production of the permeability-increasing mediator(s).

We conclude that vascular changes in inflammatory reactions should be considered in terms of two types of chemical mediators—mediators which are predominantly vasodilators and mediators which are important for their vascular permeability-increasing activity. The amount of plasma exudation is dependent on the level of both types of mediators; and it follows that oedema can be suppressed by inhibiting the production, or action, of either type. Permeability-increasing mediators seem to be independent of the cyclo-oxygenase pathway of arachidonate (or dihomo- $\gamma$ -linolenate) metabolism. No evidence was obtained in support of the recently suggested<sup>12</sup> pivotal role for  $\text{PGG}_2$ ; in inflammation the important substances derived from arachidonate (or dihomo- $\gamma$ -linolenate) are vasodilators, probably E-type prostaglandins (although the recently discovered  $\text{PGI}_2$  cannot be excluded from a similar role). Indomethacin was found to inhibit specifically the production of vasodilator mediators. Thus, we propose that non-steroid anti-inflammatory compounds reduce inflammatory oedema as a consequence of a suppression of vasodilatation.

This work was supported by the MRC. We thank Professor B. Samuelsson for  $\text{PGG}_2$ ; Dr J. E. Pike (Upjohn) for  $\text{PGE}_1$  and  $\text{PGE}_2$ ; and Mrs E. Baister (Sandoz) for bradykinin.

## Ovulation in rhesus monkeys suppressed by intranasal administration of progesterone and norethisterone

THE importance of various brain structures in the regulation of secretion of gonadotropins<sup>1–3</sup> and the presence of steroid hormones in the cerebrospinal fluid (CSF)<sup>4–5</sup> suggest that a method for delivering steroids into the CSF might be useful in the control of fertility. Steroids can enter the cerebral components rapidly after intranasal administration and their concentrations are higher than after intravenous injection<sup>6</sup>. We report here that progesterone and norethisterone given intranasally can prevent ovulation in rhesus monkeys.

Our studies were carried out between September and March during when almost all the monkeys in our colonies have ovulatory menstrual cycles. We used adult female rhesus monkeys (5–6 kg) which had experienced at least two successive ovulatory menstrual cycles of normal duration (20–33 d) (determined by monitoring circulating levels of progesterone throughout the menstrual cycles).

Two steroids, progesterone, a naturally occurring ovarian hormone and norethisterone, a synthetic progestogen widely used in hormonal contraception were

**Fig. 1** Effects of spraying progesterone intranasally in rhesus monkeys. Serum profiles of oestradiol and progesterone throughout the menstrual cycle are shown for one monkey representative of each of the four treated groups. Ovulation was suppressed only in the monkey given  $2\mu\text{g d}^{-1}$ . Black bars on x axis indicate menstruation. a, Control monkey no. 388; b, monkey no. 695,  $2\mu\text{g d}^{-1}$ ; c, monkey no. 690,  $10\mu\text{g d}^{-1}$ ; d, monkey no. 699,  $30\mu\text{g d}^{-1}$ .

**Fig. 2** Effects of spraying norethisterone intranasally in rhesus monkeys. Serum profiles of oestradiol and progesterone throughout the menstrual cycle are shown for one monkey representative of each of the three treated groups. Ovulation was suppressed only in the monkey given  $9 \mu\text{g d}^{-1}$ . Black bars on x axis indicate menstruation. *a*, Control monkey no. 705; *b*, monkey no. 703,  $3 \mu\text{g d}^{-1}$ ; *c*, monkey no. 695,  $9 \mu\text{g d}^{-1}$ .

dissolved in a mixture of ethanol:propylene glycol:water (1:1:3). A constant volume (0.5 ml) of this mixture was put into a glass atomiser (Brovon Inhaler, Moore Medicinal Products Ltd), which was inserted into one nostril of a conscious monkey seated on a restraining chair. The mixture was sprayed into the nostril for 10 s by connecting the atomiser to a nitrogen source regulated to deliver the inert gas at a constant pressure of  $0.25 \text{ kg cm}^{-2}$ . Before use, each spraying device was calibrated to deliver the drug for 10 s. The amount of steroid administered to each animal was regulated either by varying the concentration of the steroid in the solvent or by repeated spraying for periods of 10 s. Controls were sprayed with the solvent alone.

The effects on ovulation were determined by measuring serum levels of oestradiol and progesterone in blood samples taken daily throughout the menstrual cycle, as well as by visual observation of the ovaries after laparotomy on day 17 of the menstrual cycle. Circulating levels of progesterone below  $2 \text{ ng ml}^{-1}$  serum together with the regressed state of ovaries at laparotomy were taken as indicative that ovulation had been suppressed. It was assumed to have occurred when circulating levels of progesterone were greater than  $3 \text{ ng ml}^{-1}$  serum and up to  $5\text{--}6 \text{ ng ml}^{-1}$ , and when at the same time one of the ovaries was enlarged and had a newly formed corpus luteum.

Among monkeys treated with progesterone, ovulation was always suppressed by  $2 \mu\text{g d}^{-1}$  and also in two out of six cases when  $10 \mu\text{g d}^{-1}$  was given. Ovulation occurred in four of the six monkeys given  $10 \mu\text{g d}^{-1}$  as well as in all those given  $30 \mu\text{g d}^{-1}$  (Table 1, Fig. 1).

In the monkeys treated with norethisterone, ovulation was unaffected by  $3 \mu\text{g d}^{-1}$  but was suppressed in all cases when  $9$  or  $17 \mu\text{g d}^{-1}$  was given (Table 1, Fig. 2).

These results show that intranasal administration of steroids can suppress ovulation. The two steroids had different effects: progesterone suppressed ovulation at the lowest dose but not in all animals at higher doses. Norethisterone was effective only at the two higher doses. The

different effects of progesterone is not surprising in view of its ability to inhibit or facilitate gonadotropin secretion depending on circumstances. When administered to monkeys after oestradiol, it inhibits the oestrogen-induced surge of luteinising hormone (LH)<sup>7</sup>; if given in conjunction with oestradiol, it significantly advances this surge<sup>8</sup>. A facilitatory effect of progesterone on LH secretion has also been demonstrated in women<sup>9,10</sup>. In contrast, there is evidence that progesterone inhibits gonadotropin secretion and thus blocks ovulation in monkeys<sup>7,11</sup> and women<sup>12</sup>.

Further work is needed to explain the two dose-related, pharmacological effects of progesterone which we have observed.

## Metalloimmunoassay

THE disadvantages encountered with radioisotopes, such as high costs, health hazards, limited variety of useable isotopes, short shelf-life of the labelled antigens and difficulties of introducing the radioactive isotope on to the antigen molecule, have stimulated the search for non-isotopic methods in immunological work<sup>1</sup>. We report here on the feasibility of a novel non-isotopic system for immunochemical studies and its possible use in immunoassays. The basic concept of the new system is the use of metal atoms in the form of their organometallic or co-ordination complexes as labelling agents for haptens or macromolecular antigens.

The extensive chemistry of transition metal-organic complexes developed during the past two decades should provide a rich and versatile source for the synthesis of 'tailor-made' metal-labelled antigens, which would be free of the disadvantages of radioisotopes. The metal-labelled antigens are designated metallo-antigens and/or metallohapten and we suggest that the immunoassay based on these reagents be called metalloimmunoassay (MIA).

The basic requirements for a metalloimmunoassay are (1) preparation of reagents (antibodies and metallohapten) and (2) development of a method for quantifying the metal content. The metallohapten (Ag-M) and the unlabelled antigen (Ag) react with the specific antibodies, according to the competitive protein-binding equations (1) and (2).

After separation of the free, unbound antigen (Ag-M, Ag) from the antibody-antigen complexes (Ab-Ag-M, Ab-Ag), the amount of metal present in the bound (B) or free phase (F) can be determined by suitable analytical methods such as emission, absorption and fluorescence spectrometry, electrochemical methods and neutron activation. Preparation of a calibration curve plotted for standardised amounts of metallohapten and unlabelled antigen provides the means of determining the quantity of analysed substance in unknown samples.

Typical examples of reagent preparations performed during development of a metalloimmunoassay are illustrated in Fig. 1. The oestrogen steroids, oestrone (Ia), oestradiol-17 $\beta$  (Ib) and oestriol-16 $\alpha$ , 17 $\beta$  (Ic) were transformed in high yields (>80%) into their respective 3-O-carboxymethyl derivatives (IIa-c), as well as into oestradiol-17 $\beta$  hemisuccinate (IVb) and oestriol-16 $\alpha$ , 17 $\beta$ -hemisuccinate (IVc). These carboxylic acid derivatives were used for the preparation of bovine serum albumin (BSA) conjugates. The production of antisera (in rabbits) and determination of their titre and specificity by free radical immunoassay<sup>2</sup> were carried out as described previously<sup>3</sup>. The antibodies were insolubilised by reaction with cyanogen bromide-activated Sepharose 4B (Pharmacia)<sup>4</sup> in order to provide a convenient method for separation of free, unbound Ag-M from the antibody-antigen complex.

The same carboxylic acid derivatives (IIa-c and IVb-c) as well as the amino derivatives III and IVa were labelled with various metal complexes to form the oestrogen-metallohapten some of which are shown in Fig. 2. Also shown are examples of cannabinoid and barbiturate metallohapten. The structures of the compounds

reported here were characterised by routine analytical procedures. BSA, as a representative protein molecule, has been labelled with both iron and manganese complexes, in a 1:20 molar ratio BSA:metal complex.

Atomic absorption spectrometry<sup>5</sup> was used for detection and quantification of metal concentrations in solutions containing metallohapten. The use of flameless-operation instruments (Perkin Elmer 403 with HGA-70 graphite furnace and Instrumentation 351 with 455 flameless unit and programable calculation data system kit 42168-02) enabled us to obtain satisfactory calibration curves in the metal concentration range 2-50 ng ml<sup>-1</sup>. This corresponds to unlabelled hapten concentrations in the range 20-500 ng ml<sup>-1</sup>, since the metal content is on the average about 10-20% of the molecular weight of the metallohapten. This concentration range is suitable for the detection of a relatively large number of urinary metabolites such as oestriol (in pregnancy urines), morphine, barbiturates, amphetamine and cocaine, without previous extraction and concentration operations. But, in this early stage of development and given the currently commercially available atomic absorption spectrometers, MIA cannot be used for the detection of picogram hapten concentrations, as can be achieved with radioimmunoassays<sup>6</sup>. Further work may improve detection limits.

Some indication of methodology can be obtained from a brief description of one of the procedures using reagents mentioned above. Standardised solutions of the iron-containing oestradiol-17 $\beta$ -succinate metallohapten, VII, in 0.01 M phosphate buffer (pH 7.3) with 15% dimethylformamide, yielded an atomic absorption calibration curve, in the 0-50 ng Fe ml<sup>-1</sup> concentration range, with a linear regression equation  $y = 1.731x + 42.88$  and a correlation coefficient  $r = 0.9977$ . A Sepharose-bound anti-oestradiol-17 $\beta$  hemisuccinate antibody preparation was titrated with standard solutions of metallohapten, VII, Vortex-mixed, incubated (30 min at room temperature) and centrifuged (1 min at 3,000 r.p.m.).

Aliquots (20-30  $\mu$ l) from the supernatant were injected into the graphite furnace of the atomic absorption spectrometer to measure the amount of free metallohapten, Ag-M. To determine inhibition (%) of metallohapten binding, a similar experiment was carried out using a constant concentration of metallohapten VII and increasing added amounts of unlabelled steroid IVb. With the

Fig. 1 Outline for synthesis of oestrogen haptens, their protein conjugates and metallohapten.

Fig. 2 Examples of metallohaptenes.

antisera used in this experiment and hapten concentrations of  $0.1\text{--}1\ \mu\text{g ml}^{-1}$ , a molar ratio unlabelled steroid to metallohapten of 1.31:1 was required to obtain about 44% inhibition of metallohapten binding. These and similar data demonstrate the feasibility of the concept and preliminary efforts to optimise the assay conditions have been promising.

## Homology of (murine) H-2 and (human) HLA with a chicken histocompatibility antigen

THE major histocompatibility complex (MHC) is a cluster of genes controlling a variety of immunological and non-immunological phenomena<sup>1</sup>. Membrane-bound glycoprotein products of the MHC genes are of two classes: molecules of one class consist of 44,000 MW polypeptide chain which is non-covalently associated with a smaller (12,000) chain of  $\beta_2$ -microglobulin<sup>1</sup>; molecules of the second class consist of two polypeptide chains of 33,000 and 28,000

MW<sup>1</sup>. The MHC was originally discovered in the mouse<sup>2</sup>, where it is referred to as the histocompatibility-2 or H-2 system<sup>3</sup>. Later, similar systems were described in man, rhesus monkey, chimpanzee, rat, dog, rabbit and guinea pig; and, in fact, may exist in most, if not all, mammalian species<sup>4</sup>. Furthermore, clusters of genes controlling graft rejection, mixed lymphocyte reaction (MLR), immune responsiveness, and complement activity have also been reported in the chicken<sup>5</sup> and *Xenopus*<sup>6</sup>. It is tempting to speculate that these gene clusters controlling immune functions form a single evolutionary line from more primitive ancestral genes in lower vertebrates to the HLA complex in man and the H-2 complex in the mouse<sup>7</sup>. Proof of such a relationship exists for the MHC of man and mouse, where the H-2 and HLA systems show considerable amino acid sequence homology in both classes of molecules<sup>7</sup>. Because of the relative closeness of the two species (H-2 and HLA), homology is not surprising. We have investigated whether the homology extends to other vertebrate classes, such as birds: for example, is the chicken B system a true evolutionary homologue of H-2 or HLA?

Molecules isolated with the use of anti-B sera from chicken lymphocytes were used for amino acid sequence

Fig. 1 SDS-PAGE of <sup>125</sup>I-labelled B antigen precipitated from lysates of radioiodinated chicken splenocytes. analysis. White Leghorn chickens of the SC strain (Hyline SC; B<sup>2</sup>B<sup>2</sup>), 1–4 months old, were killed, spleen cell suspension prepared<sup>8</sup>, and  $0.5 \times 10^8$ – $3 \times 10^8$  cells labelled with single amino acids as described previously<sup>8</sup>. Cells were lysed in 0.5% Nonidet P40 (NP40) (Gallard Schlesinger) ( $10^8$  nucleated cells ml<sup>-1</sup>) and the lysates centrifuged and dialysed for 16–24 h at 4 °C against phosphate-buffered saline (PBS) pH 7.3. Lysates were centrifuged and the acid-precipitable radioactivity determined<sup>8</sup>. They were then treated with rabbit antisera containing antibodies against chicken Ig (RACIg). Complexes were precipitated by the addition of goat anti-rabbit Ig (GARIG). Precipitates were removed by centrifugation and the supernatants treated with anti-B serum or normal chicken serum (control) and RACIg. The anti-B serum was produced by the immunisation of B<sup>2</sup>B<sup>2</sup> chickens with B<sup>2</sup>B<sup>2</sup> cells and was extensively absorbed by red blood cells to remove non-B activity. Precipitates were washed, dissolved, and electrophoresed on 7.5% SDS-polyacrylamide gels (SDS-PAGE) at 4 mA for 16 h. Gel peaks were extracted, lyophilised, and subjected to automated sequencing on a Beckman 890C sequencer using a DMAA programme<sup>9</sup>. Samples from the sequencer were counted in Beckman Cocktail D. There was no interconversion of the radiolabels, as judged by back hydrolysis and amino acid analysis of portions of the immunoprecipitates<sup>8</sup>.

In approximately 20 separate labellings, the radioactivity in the anti-B precipitate represented 1–5% of the acid precipitable radioactivity. As shown in Fig. 1, analysis of the anti-B precipitates indicated the presence of molecules of 44,000, 26,000, and 12,000, consistent with previous studies of the chicken B antigens by Ziegler and Pink<sup>9</sup>. The 44,000 molecule presumably represents the H chain of the B antigen and the 12,000 molecule, the  $\beta_2$ M analogue. The 26,000 MW peak, which was generally small and occasionally absent may represent the Ia analogue<sup>9</sup>.

As shown in Fig. 2, eight assignments were made in the N-terminal 27 residues of the molecule. Although more than one amino acid was not found at any one position, the phenylalanine at 8 and the tyrosine at 22 remain tentative, because of the significantly lower yields at these positions compared with the others. It is possible that two distinct molecules are being sequenced (analogous to the D and K ends of H-2), only one of which has a phenylalanine at position 8 or a tyrosine at position 22.

Figure 2 also compares the partial chicken B sequence with the guinea pig GPLA<sup>10</sup>, two mouse H-2 molecules<sup>8,11–14</sup>, and two human HLA molecules<sup>15–17</sup>. Of the five residues which are identical in the first 27 residues of H-2, HLA, and GPLA, three (residues 3, 6, 7) and possibly four (residue 8) are also identical in the chicken B

sequence. Tyr at position 27 is homologous with both mouse alleles and GPLA. The only definite difference is in the Val–Met interchange at position 12. Proline, at position 15, has not been tested in the chicken. Tyr, a tentative assignment in position 22, is homologous with H-2K<sup>b</sup> and Arg, in position 9, shows no homology with the other proteins. This is not surprising as position 9 is presently the most variable position in transplantation antigens. The high degree of homology among those residues shared with the human, guinea pig, and mouse histocompatibility antigens strongly supports the notion that the B system, which diverged from the H-2-HLA precursor 75–200 Myr ago, is the evolutionary homologue of H-2, HLA, and GPLA.

## Depurination decreases fidelity of DNA synthesis *in vitro*

DEPURINATION of DNA results from the breakage of the glycosidic bond between the purine base and the deoxyribose moiety of the purine nucleotides without disrupting the structural integrity of the phosphodiester backbone. Measurements of the rates of depurination of both synthetic polynucleotides and natural DNA in various conditions *in vitro* suggest that this damage to DNA is a frequent cellular event<sup>1</sup>. The *in vivo* rate constant has been estimated<sup>1</sup> to be of the order of  $1.8 \times 10^{-9} \text{ min}^{-1}$ . Alkylation<sup>2,3</sup> and specific glycosidases<sup>4,5</sup> increase the depurination rate constants of those altered bases to  $0.08\text{--}1.4 \times 10^{-3}$  and  $4.0 \times 10^{-3}$ , respectively. We have therefore been concerned with the possible consequences which may result during replication, repair or transcription when the template contains unrepaired apurinic sites. The biological effects of depurination are not clear. Depurination of DNA has been equated with strand breakage, a potentially lethal lesion<sup>6,7</sup>, but other evidence indicates that the apurinic site may be quite stable in cells with a half life of up to several months<sup>8,9</sup>. It is possible, therefore, that depurination of DNA can be a mutagenic event. Mutagenesis by depurination might occur either by an insertion of an incorrect nucleotide opposite the apurinic site or by a deletion at that point during DNA replication or repair. In view of the potentially large number of apurinic sites and their apparent stability, we investigated the effects of depurination of DNA on the fidelity of DNA synthesis *in vitro*. Recent reports suggest that modification of polynucleotide or DNA templates by various agents, including chemical carcinogens and ultraviolet irradiation, may affect the fidelity of DNA synthesis<sup>10-12</sup>. We report here that depurination of the synthetic polynucleotide poly d(A-T) results in a decrease in the fidelity of DNA synthesis *in vitro* using the DNA polymerase from avian myeloblastosis virus (AMV). This is the first demonstration of a possible relationship between depurination and mutagenesis through incorporation of non-complementary nucleotides during DNA synthesis *in vitro*.

The effect of depurination of poly d(A-T) on the fidelity of DNA synthesis with AMV DNA polymerase is shown in Table 1. Poly d(A-T) was depurinated by exposure to heat and acid, and the fidelity of DNA synthesis was measured by the simultaneous incorporation of the complementary ( $\alpha\text{-}^{32}\text{P}$ -dTTP) and non-complementary ( $^3\text{H}$ -dGTP) nucleotides. With the non-depurinated template, AMV DNA polymerase incorporated one molecule of non-complementary nucleotide for every 4,060 molecules of complementary nucleotide. The number of non-complementary nucleotides incorporated relative to the number of complementary nucleotides incorporated (error rate) increased in direct proportion to the extent of depurination. The error rate increased from 1/4,060 to 1/1,500 as a result of depurination (Table 1, experiment 1).

The reaction requirements for the incorporation of non-complementary nucleotide with either depurinated or non-depurinated templates are shown in Table 2. The incorporation of non-complementary nucleotide was dependent on  $\text{Mg}^{2+}$ , dTTP, enzyme and template. Elimination of any of these components markedly reduced incorporation of non-complementary nucleotide. The requirements for incorporation of non-complementary nucleotide are similar for both the depurinated and non-depurinated templates, and suggest that polymerisation is required for the incorporation of non-complementary nucleotides.

The effect of depurination on the rates of incorporation of the complementary and non-complementary nucleotides is shown in Fig. 1. The rate of incorporation of both

the complementary and non-complementary nucleotides were lower with the depurinated templates as compared with the non-depurinated template. Moreover, the rates were decreased in proportion to the extent of depurination. The coordinate incorporation of complementary and non-complementary nucleotides for each template suggests that these errors are evenly distributed during synthesis. Also, with each template, the incorporation of non-complementary nucleotide relative to the complementary nucleotide was constant with time of incubation, so the increase in error rate due to depurination was not simply the result of diminished synthesis. On the contrary, when the time of incubation was varied so that net synthesis with each modified template was the same (Table 1, experiment 2), depurination caused an absolute increase in the incorporation of non-complementary nucleotides.

The results presented here demonstrate a possible relationship between depurination of DNA and error in DNA replication. The fidelity of DNA synthesis with AMV DNA polymerase is decreased as a result of depurination of the poly d(A-T) template (Table 1, experiment 1). This mis-incorporation is also shown to be directly proportional to the extent of depurination (Table 1, experiment 2). Deletion experiment (Table 2) and kinetic studies (Fig. 1), suggest that the incorporation of non-complementary nucleotides is dependent on polymerisation and occurs randomly. Preliminary results indicate that a similar increase in mis-incorporation occurs using other depurinated templates and other DNA polymerases.

An analysis of the net mis-incorporation relative to the number of apurinic sites yields a ratio of 1 error for every

\*Depurination of  $^3\text{H}$ -dA-labelled and unlabelled poly d(A-T) templates at a concentration of  $1 \text{ mg ml}^{-1}$  was carried out at pH of 2.75 and a temperature of  $55^\circ\text{C}$ . The release of  $^3\text{H}$ -adenine was measured by thin layer chromatography with cellulose plates and solvent containing *n*-butanol, isobutyric acid, 25% ammonia and water (3.0 : 1.5 : 0.1 : 1.0). The rate of depurination was 0.1% per min. No measurable depurination or change in error rate was achieved with either heat or acid treatment alone.

†Error rate = pmol dGMP incorporated / pmol dTMP incorporated.

‡Fidelity assays were performed in duplicate, were incubated at  $37^\circ\text{C}$  for 60 min and contained (final volume  $25 \mu\text{l}$ ): 50 mM Tris-HCl, pH 7.8; 5 mM  $\text{MgCl}_2$ ; 25  $\mu\text{M}$  dATP; 25  $\mu\text{M}$   $\alpha\text{-}^{32}\text{P}$ -dTTP (20 d.p.m.  $\text{pmol}^{-1}$ ); 25  $\mu\text{M}$   $^3\text{H}$ -dGTP (50,000 d.p.m.  $\text{pmol}^{-1}$ ); 2  $\mu\text{g}$  poly d(A-T) (modified as noted in the table); and 25  $\mu\text{g}$  homogeneous AMV DNA polymerase. The reactions were terminated, washed and processed for determination of acid precipitable radioactivity as previously described<sup>13</sup>. Incorporation in the absence of incubation was 0.5 pmol dTMP and 0.0134 pmol dGMP which were subtracted from the values listed.

§Assay conditions were as described above with the exception of time of incubation which was 30 min, 40 min, 50 min, 60 min, and 120 min for the 0.0%, 1.1%, 2.2%, 5.0% and 10.1% depurinated templates, respectively.

**Fig. 1** Assay conditions were as described in the legend to Table 1 with the exception of time of incubation which was varied as shown. *a*, 0% depurination; *b*, 1.7% depurination; *c*, 5.0% depurination; *d*, 10.1% depurination. ●, Incorporation of dTMP; ○, dGMP incorporated.

500 apurinic sites. This frequency is lower than would occur if any one of the three nucleotides in the reaction mixture was incorporated randomly at each apurinic site. Several plausible explanations can account for this observation. First, there may be something unique about 1 in every 500 apurinic sites leading to misincorporation. Second, there may be a looping-out phenomena at most apurinic sites, producing deletions which we cannot monitor. Finally, factors other than hydrogen bonding between base pairs may be involved in base selection so as to select the complementary base rather than the non-complementary base. A detailed analysis of each of these and other possibilities is currently under investigation.

The increased mis-incorporation by DNA polymerases with depurinated templates *in vitro* raises the possibility that similar events may take place *in vivo* with mutagenic effects. A spontaneous depurination rate constant of

$1.8 \times 10^{-8} \text{ min}^{-1}$  although quantitatively small may be significant. If one assumes that the DNA of a mammalian cell contains  $10^9$  purine residues, this rate would produce two apurinic sites per min per cell. Alkylation in conjunction with specific glycosidases could increase this rate to more than 50 apurinic sites per min per cell. The large number of apurinic sites with miscoding potential produced by the action of chemical carcinogens, either spontaneously or in conjunction with glycosidases, may be a common mechanism of action of chemical carcinogens leading to mutations and/or carcinogenesis.

## Membrane-bound carotenoid in *Micrococcus luteus* protects naphthoquinone from photodynamic action

ALTHOUGH carotenoid pigments are widely distributed in nature, their function is little understood. Studies of non-photosynthetic bacteria have led to the conclusion that these pigments are present in the plasma membrane where they protect membrane components from photo-oxidation. We report here a study of detergent-extracted carotenoid which is not protein-bound but associated with membrane lipid. The lipid-carotenoid micelles are shown to protect naphthoquinones from photodestruction, a function attributed to the native pigment.

Two major biological roles have been assigned to carotenoids in plants and prokaryotes. In photosynthetic organisms, these pigments are involved in trapping light energy<sup>1</sup>. A more general role applicable to both photosynthetic and non-photosynthetic cells, is protection from photodynamic action. Thus in photosynthetic bacteria, carotenoid-less cells, obtained by mutation or by the use of inhibitors, were killed when illuminated in aerobic but not anaerobic conditions<sup>2,3</sup>. In contrast, carotenoid-containing cells remained viable. Evidence suggested that bacteriochlorophyll acted as photosensitizer<sup>4</sup>. In non-photosynthetic bacteria early experiments showed that carotenoid-less cells were killed by light only when low concentrations of a suitable sensitising dye were added<sup>5</sup>. Subsequently, high light intensities in the absence of added sensitizer were found to kill carotenoid-less strains<sup>6</sup> while carotenoid-containing cells were afforded protection. It may be postulated that a membrane-bound pigment such as a flavoprotein or cytochrome was acting as the endogenous photosensitizer<sup>7</sup>. In *Micrococcus luteus* (*Sarcina lutea*) a study of the effects

A 15 ml sample of dialysed emulphogene extract was added to the discontinuous sucrose gradient column prepared according to the method of Hjerten<sup>19</sup> but containing an additional sucrose layer of 21% sucrose 0.56 M NaCl. Tris-citrate buffer, pH 8.6, 0.04 M was used as buffer. 240V (13 mA) were applied to the column for 20 h at 4 °C. Fractions were withdrawn from the column as shown. Nitrogen was determined by the ninhydrin method of Jacobs<sup>23</sup> and the protein content calculated assuming a 16% nitrogen content and no nitrogen contribution from phospholipid. Phospholipid was derived from the phosphorus content<sup>24</sup> assuming that the phospholipid contained 4% phosphorus. Carotenoid was obtained assuming an  $A_{1\text{cm}}^{440} = 2,500$  at 447 nm and an arbitrary molecular weight of 600.

of light on respiration in the presence of the dye toluidine blue showed that endogenous carotenoid partially protected several sites in the respiratory chain<sup>8</sup>. Using high light intensities and relying on endogenous sensitizers, carotenoid protected one photosensitive site, the respiratory quinone, menaquinone<sup>9,10</sup>.

Although several authors have suggested that the carotenoid pigment located in the plasma membrane is specifically associated with protein or lipoprotein, this has rarely been shown<sup>11,12</sup>. We have therefore attempted to isolate and purify the carotenoid pigments of *M. luteus* in a form similar to that *in vivo* using a mild non-ionic detergent, emulphogene (Mulgofer BC720). Although non-ionic detergents have been shown to remove lipid from membrane lipoproteins<sup>13</sup>, complete removal is not always achieved even at high concentrations<sup>14,15</sup>.

Overnight shake cultures grown at 28 °C on nutrient broth were used to prepare plasma membranes by mild osmotic shock after lysozyme treatment<sup>10</sup>. The membranes were extracted with 0.6% emulphogene for 35 min at room temperature which solubilised the bulk of the major carotenoids (sarcinaxanthin, sarcinaxanthin mono-D-glucoside and decaprenoxanthin<sup>16,17</sup>). The membranes themselves retained their integrity after extraction as viewed by either phase contrast or electron microscopy using negative staining (compare erythrocyte ghosts<sup>18</sup>). The extract showed a large number (at least 20) of protein bands when subjected to electrophoresis at pH 8.6 in 7.5% acrylamide gels containing 0.1% (w/v) emulphogene. The absorption maxima of the extracted carotenoid (418, 447 and 476 nm) are the same as those of the membrane-bound pigment obtained by difference spectroscopy of membranes from the wild-type and a carotenoid-less mutant. Sucrose gradient electrophoresis<sup>19</sup> of the extract at pH 8.6 for 20 h gave fractions with carotenoid, protein and phospholipid contents shown in Table 1. The carotenoid band was diffuse, low in protein

content but rich in phospholipid. On analytical acrylamide electrophoresis at pH 8.6, the carotenoid fraction (I and II, Table 1) showed a single amidoschwartz-staining protein component running independently of the carotenoid band. In electrophoretic studies, the carotenoid band seemed translucent, was anodic between pH 3.1 and 8.6 and was evidently associated with phospholipid.

Fractionation of the extract on DEAE-cellulose at pH 8.6 resulted in a discrete carotenoid fraction running substantially in front of the flavoproteins (NADH and malate dehydrogenases). The carotenoid fraction had a substantial phospholipid content (12.5  $\mu\text{g}$  per  $\mu\text{g}$  carotenoid) but was low in protein (2.5  $\mu\text{g}$  per  $\mu\text{g}$  carotenoid). Partition of the emulphogene extract in a polymer system, dextran-Ficoll-polyethyleneglycol-KCNS<sup>20</sup> resulted in the carotenoid partitioning, together with the phospholipid, in the hydrophobic polyethyleneglycol phase. This phase contained protein which migrated as a single band independently of the carotenoid on acrylamide gel electrophoresis.

Using the emulphogene extract or the carotenoid phase after polymer partition and dialysis, it has been possible to demonstrate the protection of naphthoquinone (phyloquinone, vitamin K<sub>1</sub>) by carotenoid. The quinone was added to the carotenoid preparation, briefly sonicated and assayed before and after irradiation with blue (460  $\pm$  5 nm) light. The loss of quinone was compared with that in a similar preparation from a carotenoid-less mutant of *M. luteus* (Table 2). The loss of quinone was clearly greater in the carotenoid-less preparation. Some loss of quinone in the carotenoid system is to be expected since the method of preparation did not ensure that all quinone molecules were in association with carotenoid. By contrast, addition of quinone to an ethanolic extract of the organism did not result in protection of quinone by carotenoid.

Since in our analytical studies we find carotenoid migrating with phospholipid, it is probable that in the detergent

**Table 2** Irradiation of phyloquinone (vitamin K<sub>1</sub>) by blue light

	Before irradiation ( $\mu\text{g ml}^{-1}$ )	After irradiation ( $\mu\text{g ml}^{-1}$ )	% Loss of quinone
Quinone in extract from pigmented membranes	17.5	16.9	3
Quinone in extract from carotenoid-less membranes	17.6	13.6	23

Phyloquinone in 0.1 ml ethanol was added to a carotenoid extract after partition<sup>20</sup> into a polyethyleneglycol phase. The mixture was sonicated to form a micellar system of carotenoid and quinone. The preparation was irradiated with blue light (460  $\pm$  5 nm) for 12 min at 15 W m<sup>-2</sup>, the preparation having a 1 cm light path. The quinone was assayed by the borohydride reduction method of Kroger and Dadak<sup>25</sup>.

extract the carotenoid is present in phospholipid micelles. The water-insoluble naphthoquinone is likely to be held in the micelles in relatively close proximity to the carotenoid, a situation not achieved in ethanolic solution. The protection of quinone by transfer of excitation energy to carotenoid will therefore be facilitated.

In studies of respiration, the function attributed to carotenoid is protection of the quinone<sup>10</sup>. Since the extracted carotenoid carries out the same function and has the same absorption maxima as in the membrane-bound state, we believe that the bulk of the pigment is associated with membrane lipid *in vivo*. In viability studies the protective function of carotenoid has been shown to depend not only on chromophore length<sup>21</sup> but also on concentration<sup>22</sup>. Thus the bulk carotenoid seems to be necessary for photoprotection. This does not, however, rule out the possibility of small amounts of carotenoid being protein-bound<sup>12</sup> or of the pigment being associated with lipoprotein, but such states would not be essential for the protective function. We conclude that the lipid-associated carotenoid in *M. luteus* has a role in the photoprotection of naphthoquinone.

## Temperature and wavelength effects on the photochemistry of rhodopsin, isorhodopsin, bacteriorhodopsin and their photoproducts

The primary photochemical event in visual pigments has become a matter of considerable controversy<sup>1–3</sup>. We recently reviewed the various models that have been proposed and argued that the accumulated evidence strongly favours the original suggestion of Kropf and Hubbard that the primary step involves a *cis-trans* isomerisation<sup>4</sup>. Evidence for isomerisation is based on the photoequilibrium that can be established, both at 77 K (ref. 5) and at room temperature<sup>6</sup>, between rhodopsin, bathorhodopsin (its primary photoproduct), and

isorhodopsin (which contains a 9-*cis* chromophore). The equilibrium can be represented by

This strongly suggests that the isomeric configuration of the chromophore of the common bathorhodopsin intermediate is all-*trans* retinal, and thus light has isomerised the chromophore from 11-*cis* to all-*trans*.

It is of considerable interest to obtain a quantitative description of the physical processes involved in the primary photochemical event. Based on an analysis of the temperature and wavelength effects on the photochemistry of rhodopsin and protonated Schiff bases in solution, we proposed a model<sup>4</sup> describing a potential energy curve for the excited state of the visual pigment. The major conclusion of the model is that the protein moiety of the pigment efficiently channels the excitation energy of the chromophore into a single potential minimum along the 11–12 torsional coordinate.

We extend here our original experiments and analysis to the

**Fig. 1a** Absorption spectra of bovine rhodopsin in 67% glycerol and 2% digitonin at (1) room temperature and (2) 77 K. Corrections were made for scattering by subtracting the spectrum of the same sample bleached in the presence of hydroxylamine. Corrections were also made for a 7.7% solvent contraction at 77 K. The dashed line represents the quantum efficiency for bleaching rhodopsin at room temperature<sup>10,11,12</sup>. The circles represent the average of five measurements of the quantum efficiency at 77 K as described in the text. Standard deviations are given by the error bars. **b**, Isorhodopsin spectra under same conditions as in **a**. Isorhodopsin was prepared by regeneration of opsin with 9-*cis* retinal. Circles represent room temperature quantum efficiencies and triangles represent the quantum efficiencies at 77 K.

artificial pigment, isorhodopsin, and to the purple membrane protein of *Halobacterium halobium*, bacteriorhodopsin. The results for isorhodopsin provide a strong independent confirmation of the original model. Moreover, our analysis of bacteriorhodopsin photochemistry suggests a protein induced *cis-trans* isomerisation for that pigment as well.

Our experimental approach is to test the effects of temperature and excitation wavelength on the absolute yield of forming the bathorhodopsin from both rhodopsin and isorhodopsin as well as the purple membrane protein. The amount of isorhodopsin and rhodopsin converted to bathorhodopsin by a low dose irradiation at 77 K was determined by warming the sample to room temperature (where the bathorhodopsin decays to all-*trans* retinal and opsin) and measuring the amount of unbleached pigment remaining. The amount of the purple membrane protein converted to its bathorhodopsin, K, was calculated from the absorption of the mixture formed after a short irradiation using the extinction coefficients of the purple membrane and K (shown in Fig. 2). Quantum yields were calculated according to Dartnall<sup>8,9</sup> using rhodopsin as an actinometer and correcting for changes in extinction coefficient with temperature (Figs 1a and 1b). Quantum fluxes at longer wavelengths were determined with a rhodopsin calibrated photodiode.

As shown in Figs 1a and 2, we found that the quantum yield of the primary photo-event of rhodopsin and the purple membrane protein is, within experimental error, independent of excitation wavelength and temperature over a 220 K range. Moreover, Fig. 2 shows the quantum yield of the photoreversal from the bathorhodopsin K to the purple membrane pigment is also independent of temperature. On the other hand, the quantum yield for bleaching isorhodopsin (which has no wavelength dependence at room temperature) shows a significant decrease at lower temperatures (Fig. 1b). This lower quantum yield at 77 K was also wavelength dependent, the yields being smaller as wavelength increased.

The wavelength and temperature independence of the bleaching of rhodopsin strongly suggests that *cis-trans* isomerisation takes place after complete thermal relaxation and requires no activation energy. This situation may be achieved by efficiently channelling the excited system into a minimum, along a barrierless potential curve connecting the *cis* and *trans* configurations as shown in Fig. 3. This conclusion was also suggested by the observation that the quantum yields for the forward

and back

reactions nearly sum to unity<sup>4</sup> which implies that most ( $\phi_1 \approx \phi_2 \approx 1$ ) excited rhodopsin and bathorhodopsin molecules populate a common point on the excited state potential surface. (This can be easily seen since  $\Phi_{R \rightarrow B} = \phi_1 \gamma_1$ ,  $\Phi_{B \rightarrow R} = \phi_2 \gamma_2$  and  $\gamma_1 + \gamma_2 = 1$ . Thus,  $\Phi_{R \rightarrow B} + \Phi_{B \rightarrow R} = 1$  only when  $\phi_1 \approx \phi_2 \approx 1$ ).

The general form of the potential curve shown on the left side of Fig. 3 is amenable to more quantitative analysis. Using the absolute and relative quantum yields at 77 K (see Fig. 3) we find  $\phi_1 = 1.0$ ,  $\phi_2 = 0.9$ ,  $\gamma_1 = 0.67$  and  $\gamma_2 = 0.33$ . Moreover, the temperature independence of the  $R \rightarrow B$  photoisomerisation shows that these values are accurate at room temperature as well (with the possible exception of  $\phi_2$  which cannot be determined at room temperature). Thus, the left side of Fig. 3 provides the first detailed characterisation of the primary photochemistry of rhodopsin.

The fact that  $\phi_2 = 0.9$  (which requires that  $\Phi_{R \rightarrow B} + \Phi_{B \rightarrow R}$  be slightly less than unity) is due to the leakage ( $\phi_3$ ) of bathorho-

**Fig. 2** Absorption spectra at 77 K in 67% glycerol of (1) the purple membrane protein and (2) its primary photoproduct, the K intermediate. The K spectrum was determined from the spectrum of the 500 nm photosteady-state mixture, assuming it to be 28%K. This was determined by warming the mixture under conditions<sup>9</sup> which allow the complete conversion of K to M(412), revealing the percentage of pigment unconverted in the photosteady-state mixture. The circles represent the purple membrane protein quantum efficiency and the triangles represent the K quantum efficiency both at 77 K. The dashed lines represent the corresponding quantum efficiencies for the pigment (at  $-40^\circ\text{C}$  (ref. 9); a similar value is seen at room temperature)<sup>14</sup> and for the bathorhodopsin (at room temperature RT).

dopsin to the 9–10 torsional coordinate leading to the formation of isorhodopsin. An independent check of the numbers given above requires that an analysis of the  $B \rightleftharpoons I$  interconversion yield  $\phi_3 = 1 - \phi_2 \approx 0.1$ . Unfortunately, the temperature dependence of  $\Phi_{I \rightarrow B}$  and its wavelength dependence at 77 K (due perhaps to a small barrier along its potential surface) preclude an accurate determination of  $\phi_3$ ,  $\phi_4$ ,  $\gamma_3$  and  $\gamma_4$ . It is possible, however, to use the values of  $\Phi_{I \rightarrow B} = \phi_4 \gamma_4$  and  $\Phi_{B \rightarrow I} = \phi_3 \gamma_3$  to estimate  $\phi_3$ .

Taking an average value of  $\Phi_{I \rightarrow B} \approx 0.13$  (Fig. 1b) and the ratio  $\Phi_{B \rightarrow I} / \Phi_{I \rightarrow B} = 0.4$  determined previously<sup>4</sup> we find  $\phi_3 \gamma_3 = 0.05$ . (Thus our model yields  $\Phi_{B \rightarrow R} / \Phi_{B \rightarrow I} = \phi_2 \gamma_2 / \phi_3 \gamma_3 \approx 5$ , in complete agreement with the estimate of Yoshizawa and Wald<sup>5</sup>.) Simple numerical considerations (see Fig. 3a) now lead to the conclusion that  $\phi_3$  must be approximately 0.1, thus providing an important consistence check for the analysis of the  $B \rightleftharpoons R$  interconversion.

The most striking implication of the above analysis is the complete channelling ( $\Phi_1 = 1.0$ ) into the common minimum from excited rhodopsin molecules (11-*cis* configuration) and almost complete channelling of bathorhodopsin (all-*trans*) ( $\Phi_2 = 0.9$ ) to the 11–12 torsional coordinate accounting for the relationship  $\Phi_{R \rightarrow B} + \Phi_{B \rightarrow R} \approx 1$ . As can be seen from Fig. 2, the same relationship ( $\Phi_{PMP \rightarrow K} + \Phi_{K \rightarrow PMP} = 0.28 + 0.72 = 1$ ) also characterises the primary photoevent in light-adapted bacteriorhodopsin, both at 77 K and at room temperature (Fig. 2 and refs 9, 13, 14). Moreover, the photoreversibility of the various intermediates so characteristic of the bleaching sequence of visual pigments<sup>5</sup> is also a feature not only of the K intermediate but also of the 'M' (412 nm) intermediate of the purple membrane protein<sup>10</sup>. These striking photochemical analogies very strongly suggest a *cis-trans* geometry change as the primary photochemical step in bacteriorhodopsin.

The extremely simple photochemical behaviour of both rhodopsin and purple membrane protein should be contrasted with the complex patterns that characterise the photoisomerisation of retinal analogues<sup>15</sup> and other well studied systems such

**Fig. 3a** Potential energy diagrams for the rhodopsin, bathorhodopsin, isorhodopsin interconversions. The quantum efficiency for rhodopsin isomerisation is  $\phi_{R \rightarrow B} = \phi_1 \gamma_1$ , where  $\phi_1$  is the probability of reaching the bottom of the potential well of the excited state and  $\gamma_1$  is the probability of going to bathorhodopsin from the bottom of the well. Similar relations hold for  $\phi_{B \rightarrow R}$ ,  $\phi_{B \rightarrow I}$ , and  $\phi_{I \rightarrow B}$ . Quantum yields for the 11-12 coordinate are calculated from the 77 K data presented here and using  $\phi_{R \rightarrow B}/\phi_{B \rightarrow R} = 2.2$  (ref. 4). For the 9-10 coordinate, our room and low temperature data set limits for  $\phi_4$  between 0.22 and 1.0 leading to  $0.22 < \gamma_4 < 0.59$ ,  $0.41 < \gamma_3 < 0.78$  and then using  $\phi_3 \gamma_3 = 0.06$  we find  $0.07 < \phi_3 < 0.14$ . Thus, all values of  $\phi_3$  are consistent with  $\phi_2 \approx 0.9$ . **b**, Hypothetical energy level diagram for the purple membrane protein and its batho-product K. This diagram ignores the observed fluorescence which is thought to come from another excited state (ref. 19).

as stilbenes<sup>16</sup>. In contrast to the pigments, the quantum yields of the model compounds are strongly wavelength-dependent and can be 1-2 orders of magnitude less than those of the pigments. Thus, it seems that the protein facilitates isomerisation in the chromophore by altering the excited state potential energy surfaces and/or by modifying rates of radiationless deactivation. It is interesting in this context that the artificial pigment isorhodopsin seems to undergo a less efficient and more complex photochemistry than does rhodopsin.

The protein can also influence the ground state energy surfaces. Although free 11-*cis* and all-*trans* retinal have very similar free energies<sup>17</sup>, the opsin modifies the equilibrium conformation of the chromophore so that rhodopsin is at least 10 kcal mol<sup>-1</sup> lower in free energy than the final products, opsin and free all-*trans* retinal. Moreover, bathorhodopsin decays spontaneously to opsin + all-*trans* retinal and, thus, must be still higher in free energy than these products; this free energy must be obtained from the photon absorbed by

rhodopsin. A hypothetical ground state energy diagram is also included in Fig. 3.

The bathoprotect of the purple membrane protein must also contain a significant fraction of the absorbed photon's energy since the spontaneous decay of this photoproduct back to the original pigment is used to power a proton pump across the cell membrane<sup>18</sup>. In view of the basic similarity of this pigment and rhodopsin with respect to the chromophore structure and binding and their primary photochemistry, it is reasonable that similar energy storage mechanisms are operative in both pigments.

Recently, Peters *et al.*<sup>20</sup> have observed a deuterium-dependent decay of a transient species following picosecond stimulation of rhodopsin; they have proposed that light does not isomerise the chromophore, but rather initiates a proton transfer to it (see also ref. 3). We do not, however, believe that their data in any way rules out *cis-trans* isomerisation; indeed many interpretations of the data, other than the one they give, are possible. For example, the transient species may be due to a time-dependent shift in the absorption spectrum of bathorhodopsin, due to a relaxation of the protein/chromophore following isomerisation; that is, it could arise if the proton of the protonated Schiff base changes its orientation with respect to its counter ion or even switches its counter ion as a result of *cis-trans* isomerisation. This could account for the temperature and deuterium effects of the rate of formation of bathorhodopsin. In any case, the models Peters *et al.* propose for the primary event are incompatible with the known properties of bathorhodopsin discussed above and in ref. 4. Moreover, it is difficult to see how proton tunnelling as the only primary event would result in a stable species (at 77 K) which would not revert back to rhodopsin. Finally, Green *et al.*<sup>21</sup> have recently provided evidence that isomerisation in rhodopsin and isorhodopsin can occur in picoseconds at room temperature.

# matters arising

## Membrane initiation of DNA synthesis

HOBART *et al.*<sup>1</sup> reported convincing autoradiographic evidence that DNA replication is initiated near or on the nuclear membrane in sea urchins. In their discussion of the difference between their results and those reported by others for mammalian cells<sup>2-4</sup>, they raise the possibility that the latter results might arise from repair synthesis because, "... autoradiographic analysis cannot distinguish between replication and repair synthesis of DNA ..." and "Such a situation would confuse the interpretation of autoradiographs in determining sub-nuclear sites of replication".

It is only remotely possible that this explanation is correct. DNA repair synthesis in undamaged mammalian cells is not detectable by even very sensitive methods<sup>5</sup>, let alone autoradiography. In cells whose DNA molecules are severely damaged, repair synthesis (excision) never exceeds about 1% of the amount of semiconservative synthesis that would occur simultaneously in undamaged cells<sup>6,7</sup>; even this amount of repair synthesis would not be detectable by the electron microscope autoradiographic method used by Hobart *et al.*<sup>1</sup>.

Thus, the explanation for the results showing a difference between sites of initiation of DNA synthesis in sea urchins<sup>1</sup> and in mammalian cells<sup>2-4</sup> is very likely other than the one proposed by Hobart *et al.*<sup>1</sup>.

HOBART *et al.* REPLY: We agree with Painter and Cleaver that it seems only remotely possible that repair synthesis

of DNA could account completely for the differences between our results with sea urchins and those of others using mammalian cells. But, it remains to be determined if repair synthesis is indeed a minor activity in cells which have been maintained for prolonged periods of time in tissue culture and have been treated with various metabolic inhibitors to achieve synchronisation. In any case the results with sea urchin embryos, which are normally synchronous and in which semiconservative replication is undoubtedly the principle activity, indicate that DNA synthesis occurs on or near the nuclear membrane.

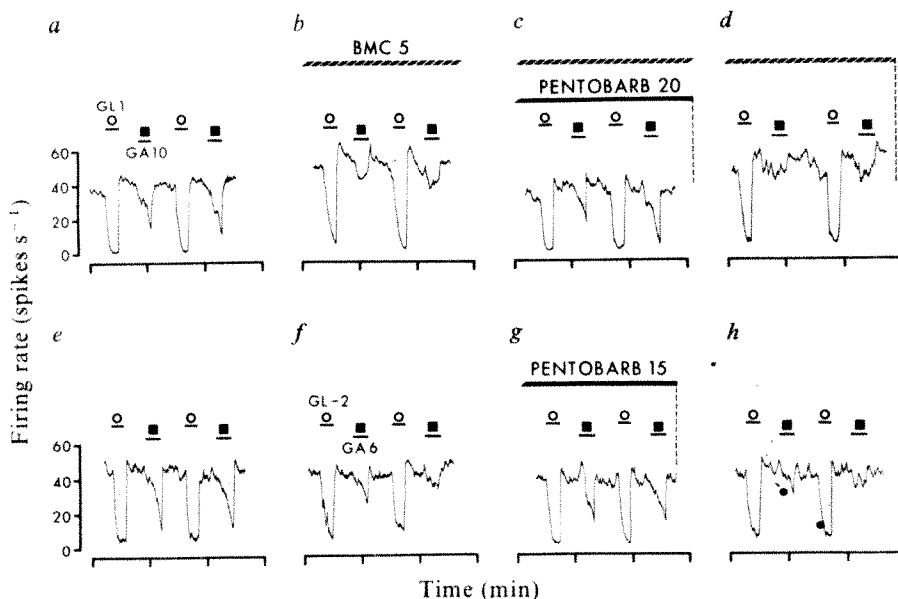

## Pentobarbitone enhancement of the inhibitory action of GABA

BOWERY and Dray<sup>1</sup> have suggested that pentobarbitone reverses the effects of the  $\gamma$ -aminobutyric acid (GABA) antagonist bicuculline methochloride (BMC), on both the superfused rat

superior cervical ganglion and rat medullary neurones *in vivo*, without potentiating the action of GABA on these tissues in the absence of BMC. Such an action does not readily account for the accentuation by pentobarbitone of inhibitions mediated by GABA in the mammalian central nervous system<sup>2</sup>, except by antagonism of an as yet undetected endogenous GABA antagonist.

We have investigated the action of pentobarbitone on 31 dorsal horn interneurons and three Renshaw cells of eight low spinal cats anaesthetised i.p. with either  $\alpha$ -chloralose and urethane (40 and 400-800 mg per kg), diallyl barbituric acid and urethane (60 and 600 mg per kg) or pentobarbitone sodium (35 mg per kg). Amino acids, acetylcholine, and pentobarbitone were administered electrophoretically from solutions in the outer barrels of seven-barrel micropipettes, the 3.6 M NaCl-containing centre barrels of which were used to record extracellular action potentials of single neurones. The following solutions were

Fig. 1 Ratemeter records of the firing of a dorsal horn interneurone in a cat anaesthetised with  $\alpha$ -chloralose and urethane. The electrophoretic ejection of glycine (GL) and GABA (GA) are indicated by the appropriate symbols, horizontal black lines and currents (nA). *b* and *c* were recorded 5 and 10 min after the commencement of the ejection of BMC which continued for 15 min, ceasing after *d*, as indicated by the broken vertical line. The ejection of pentobarbitone (PENTOBARB) commenced 3 min before *c* and again 2 min before *g*, and was also terminated at the vertical broken lines. Records *e* and *h* were 1 min after *d* and *g* respectively. Ordinates, firing rate, spikes  $s^{-1}$ , abscissae, time in min.

used: GABA (0.1, 0.2 M; pH 3), glycine (0.5 M; pH 3), L-glutamate (0.5 M; pH 7.5), DL-homocysteate (DLH, 0.2 M; pH 7.5), acetylcholine hydrobromide (ACh, 0.25 M), BMC (10 mM in 165 mM NaCl) and sodium pentobarbitone (20 mM; pH 9.5 or 250 mM in a 7 : 2 : 1 mixture by volume of water, propylene glycol and ethanol).

In confirmation of Bowery and Dray<sup>1</sup>, pentobarbitone (10–60 nA) partially reversed the antagonism by BMC of the inhibition of cell firing by GABA. With most neurones, however, in the absence of BMC, pentobarbitone ejected with the same or even lower electrophoretic currents enhanced sub-maximal inhibition of firing by GABA. Furthermore, the inhibitory action of electrophoretic glycine on many cells was also enhanced, but not to the same extent as that of GABA.

Results from one neurone are illustrated by the records in Fig. 1 of the rate of firing of a dorsal horn interneurone maintained by the continuous ejection of DLH, 8 nA. Firing was inhibited by glycine and GABA, ejected consecutively each for 7 s at fixed time intervals (Fig. 1a). During the ejection of BMC, the effect of GABA was reduced (Fig. 1b), but was restored to near control values during the simultaneous administration of pentobarbitone from an aqueous solution (Fig. 1c). This effect of pentobarbitone was reversible (Fig. 1d), as was the antagonism of GABA by BMC (Fig. 1e). Several minutes later, when the currents ejecting glycine and GABA had been reduced, in particular that of GABA to reproduce the inhibitory action observed during the ejection of BMC (compare Figs 1b, d and f), pentobarbitone also reversibly enhanced the effectiveness of GABA (Fig. 1g and h). The degree of enhancement of the GABA effect by pentobarbitone in the absence of BMC was very similar to that during the ejection of BMC.

Effects such as these, which were observed with spontaneously active cells as well as with those in which firing was maintained with DLH, glutamate or ACh, and irrespective of the anaesthetic used or whether BMC was in one of the barrels of the micro-pipettes, render unnecessary a postulate that pentobarbitone displaces BMC from receptors on central neurones<sup>1</sup>. At least in the spinal cord of the cat the increased effectiveness of GABA by pentobarbitone probably is adequate to account for the reversal of antagonism by BMC. Further experimentation will be required to determine whether this action of pentobarbitone results from interference with the cellular uptake of amino acids or from a more direct effect at postsynaptic receptors<sup>3</sup>. The importance of this latter type of action

is suggested by the frequent observation that electrophoretic pentobarbitone depressed the firing rate of neurones, and that pentobarbitone, like GABA, depolarises the terminals of group Ia afferent fibres in the cat cord (our unpublished work).

1. Bowery, N. G. & Dray, A. *Nature* **264**, 276–278 (1976).
2. Nicoll, R. A. *Nature* **258**, 625–627 (1975).
3. Ransom, B. R. & Barker, J. L. *Brain Res.* **114**, 530–535 (1976).

**BOWERY and DRAY reply**—The results of Lodge and Curtis are most interesting but, whilst we do not dispute that enhancement of responses to GABA and glycine can occur in the absence of bicuculline methochloride (BMC), in our experiment in the rat medulla we saw no clear enhancement of sub-maximal responses to GABA or glycine using expelling currents of pentobarbitone which on the same cells reversed the antagonism produced by BMC or strychnine. Pentobarbitone in all cases did not decrease the background firing rate of the cell, an observation which differs from that of Lodge and Curtis. Only when we increased the ejecting current by 2–3-fold did pentobarbitone decrease the firing rate<sup>1</sup>. It remains to be seen whether this decrease in firing results from a GABA-mimetic effect at post-synaptic receptors. It is interesting to note that the increase in firing rate produced by BMC in the Lodge and Curtis experiment (shown in their Fig. 1b) seemed to be antagonised by the ejection of pentobarbitone (c).

Although Lodge and Curtis suggest that the enhancement of responses to

GABA could account for the observed BMC reversal on dorsal horn interneurones in the cat spinal cord we believe that under our experimental conditions on spontaneously-active neurones in the rat medulla, these phenomena are separable. Some evidence in support of this comes from results we have obtained with other drugs in the superior cervical ganglion. Although the barbiturates were the most effective in reversing BMC antagonism other central depressant drugs with quite different chemical structures, for example, benzodiazepines, amitriptyline and promethazine also reduced BMC antagonism. None of these substances significantly potentiated the effect of GABA at the concentrations employed nor did they exhibit any direct GABA-mimetic activity even at >10-fold higher doses.

Experiments with nipecotic acid in the ganglion indicate that BMC reversal by pentobarbitone is probably unrelated to any inhibition of the cellular uptake of GABA. Nipecotic acid inhibits GABA uptake in this tissue and thus potentiates the response to GABA<sup>2</sup>. Unlike pentobarbitone, however, nipecotic acid will neither prevent nor partially reverse BMC antagonism and moreover will not prevent pentobarbitone reversing the action of BMC.

Two phenomena associated with the action of pentobarbitone in relation to GABA and glycine receptors have been described—first, an enhancement of the action of GABA or glycine as reported by Lodge and Curtis and others<sup>3,4</sup> and second, a direct GABA-mimetic action as described by Nicoll<sup>4</sup>. Our results suggest that a third phenomenon may occur, that of reversal of the action of convulsants which antagonise responses to GABA and glycine.

Although separation of these phenomena may not be easy in some systems our results indicate that it is possible in the rat medulla and sympathetic ganglion and may depend on the concentration of pentobarbitone employed.

## Matters Arising

Matters Arising is meant as a vehicle for comment and discussion about papers that appear in *Nature*. The originator of a Matters Arising contribution should initially send his manuscript to the author of the original paper and both parties should, wherever possible, agree on what is to be submitted. Neither contribution nor reply (if one is necessary) should be longer than 300 words and the briefest of replies, to the effect that a point is taken, should be considered.

## Best kind of Natural History

S. R. J. Woodell

*Population Biology of Plants.* By John L. Harper. Pp. xxiv+892. (Academic: London, New York and San Francisco, 1977.) £30; \$58.60.

As Professor Harper states in his preface, population biology was for almost half a century the almost exclusive preserve of zoologists. In the early part of this century, Sukatschew, Tansley and especially Clements experimented on plant populations, but thereafter most plant ecologists turned to other aspects of the subject. This might seem strange. Plants are immobile. They do not have to be captured, marked and recaptured, but whereas animals respond to environmental changes by changing numbers, plants may change in either number or size, or both. It is perhaps this plasticity that has deterred some botanists from studying their populations. Numbers can be counted, size has to be measured, usually destructively.

Harper was fortunate to come into contact early in his career with Charles Elton and his group in Oxford, and then with agronomists in Aberystwyth, to whom experimentation on plant populations was nothing new. Unlike most botanists he realised the relevance of animal population studies to plants, and acted upon it. During the past twenty-five years he, his students and co-workers have done more than anyone to set the science of plant population biology on its feet, and it is appropriate that he should write the first major book about it.

A short introductory chapter on "Experiments, Analogies and Models" sets the scene, and is followed by five major sections: on "Dispersal, Dormancy and Recruitment"; "The Effects of Neighbours"; "The Effects of Predators"; "The Natural Dynamics of Plant Populations"; and finally, "Plants, Vegetation and Evolution".

Each is complete in itself, but they are all linked by the evolutionary theme that pervades the whole book. Harper, in acknowledging his debt to Darwin, states that he thinks the third chapter of the *Origin of Species* is the best ecological text ever written. Though not all would agree with this, there is no doubt that it shows an insight into interactions between organisms that has not yet been surpassed, for all that it was written 120 years ago. Harper comments (p492): "in ecology . . . the idea of evolution as a continually operating force in ecological interactions seems to be accepted unwillingly." Sadly, this is true of many, though not by any means all ecologists; such workers as G. E. Hutchinson are outstanding exceptions. This book puts the relationship between ecology and evolution firmly back into the centre of the stage.

Every chapter in Harper's book has something to say about how plant populations interact with their total environment. With animal ecologists in mind as readers, he is constantly pointing to ways in which animal and plant populations are similar and different. Apart from the plasticity of plants, two especially interesting points he makes are that the food of green plants does not reproduce and is not the result of a reproductive process (this fundamentally affects their population biology); and that plants consist of "populations of parts" (and this cannot be said of animals except perhaps corals, and some colonial Hymenoptera).

Everyone will find much of interest here; there are ideas enough to keep several workers busy for a lifetime. If I may pick chapters which especially interested me, I would select, chapter 11, "Mechanisms of Interaction Between Species", as a most stimulating, critical and thought-provoking discussion of the problems and pitfalls

inherent in studying plant interactions. The several chapters on "The Effects of Predators" comprise an account in depth of some aspects of plant-animal interactions, a fashionable field these days after long neglect. The final section, where evolution is brought to the fore, is a fascinating development in evolutionary terms of much that has gone before.

It will be clear that I liked this book; indeed, I found it difficult to put down once I had begun it. There are small irritations. In places, it reads rather like a catalogue of experiments, though every experiment described is very relevant. Those familiar with Harper's work will be familiar with much of the content of the book, but to have it all together is very valuable; and a glance at the bibliography reveals the breadth of the literature surveyed here. Harper is not quite consistent in his acceptance in some places, and rejection in others, of anecdotal evidence. These are minor flaws. A credit is the inclusion of good chapter summaries at the beginning of the book.

'Natural History' is a much-abused term, probably largely as a result of the flood of poor quality writings on it during the last century. Yet who would deny that *The Natural History of Selborne* (Gilbert White) is a great book, or that although much of what Darwin wrote was Natural History, he was a great scientist. The Oxford English Dictionary defines Natural History thus: "A work dealing with the properties of natural objects, plants or animals; a scientific account of any subject on similar lines." In those terms, I am sure that Professor Harper will not object to his book being described as an example of the best kind of Natural History. □

S. R. J. Woodell is Lecturer in Ecology in the Botany School at the University of Oxford, UK.

## Polymer science

*Macromolecules*. Vol. 1: Structure and Properties. Pp. 532. Vol. 2: Synthesis and Materials. By Hans-Georg Elias. Pp. 131. (Wiley: London; Plenum: New York, 1977.) £24; \$42.50 each volume.

In his preface, the author describes these two volumes as a textbook, treating "the whole field of macromolecular science, from its chemistry and physics to its applications, in a not too elementary manner." To attempt this is a stupendous undertaking for a single author, but it can be said at once that the text amply justifies the claim. The original version (1971) was in German and the present text is a translation from a 1975 revised German edition—but shows no internal evidence of not having been written in English from the start.

The method adopted is that of straightforward exposition; where differing viewpoints might be held, the author usually takes a clear line, no doubt with the aim of avoiding confusion for the student. The area to be covered is vast, and within the scope of 1,100 pages most topics can receive no more than outline treatment. To enable the student to supplement this, a reading list of books and review articles is provided for each section, but there are no references to the original literature (except for historical introduction). The opportunity has evidently been taken in revision and again in translation to add recent titles to the original reading lists.

The contents of the two volumes can be described roughly as physics and chemistry, respectively; and although the work is planned as a whole, the two parts could each stand alone. Volume 1 deals with the theoretical and experimental basis of our knowledge of polymer structure, and physical properties. It is divided into three parts: structure, solution properties, and solid-state properties. Little is assumed in the way of background knowledge: chapter 5 opens with an account of X-ray scattering; and chapter 9.5 with a presentation of the basic principles of light scattering. Experimental methods are outlined, and although equipment is not described in detail, key features are frequently pointed out. Although this volume is largely concerned with principles, it is sufficiently wide-ranging to include reference to such practical matters as adhesives and glues, and the testing of insulators for resistance to tracking.

Volume 2 divides into two roughly equal parts dealing, respectively, with principles of polymerisation and individual polymers. Following an introductory chapter on general principles, the first part deals successively with polycondensations; ionic, insertion and radical

reactions, copolymerisation; and finally with reactions of macromolecules (including aging). This is a wide-sweeping survey at a very well chosen level.

The last section of the book is entitled "Polymers" and is divided into nine chapters, of which the first four deal broadly with synthetic organic polymers classified according to their main chains: carbon, carbon-oxygen, carbon-sulphur, carbon-nitrogen. The chapters are further broken down by polymer type into 25 sections, many of them further subdivided. The general method of treatment for each polymer includes monomer synthesis, polymerisation methods and mechanisms, polymer properties and reactions; all done very competently and succinctly. Final chapters extend the scope to biopolymers and inorganic chains, and serve at least to remind the student of the wide ramifications of macromolecules in nature.

Nothing could be easier for the reviewer of a work of this kind than to select a field in which he is personally expert and

to point out shortcomings and possible errors of judgement. Inevitably, when an author undertakes to review such a vast field he will succeed better with some areas than others. What is more pertinent to ask is (a) whether the work succeeds in its declared aim, and (b) what other needs it might serve. On the first of these counts, there is no doubt that any student who works systematically through this text will acquire a broad knowledge and understanding of polymer science and its applications. Spread over the three years of a Ph.D. course, it would provide a superb accompaniment to the experimental study of a limited topic. For the reviewer, its role will be that of an admirable first source of information, providing a coherently argued introduction and a guide to further reading. On both counts, it is a notable addition to polymer literature.

Geoffrey Gee

## Volcanic leitmotive

*Carbonatite-Nephelinite Volcanism*. By Michael J. Le Bas. Pp. 347. (Wiley: London, New York and Toronto, 1977.) £22; \$44.

THERE is a long standing joke that one can doze off during one of Wagner's *Ring of the Nibelungen* operas, only to wake up ten minutes later to find the same singer standing on the same spot singing the same song. One gets the same impression from Le Bas' book. No matter where one dips into it, there is a certain sameness about the text. Tortuous rock names like uncomphagrite, turjaite, melteigite, ijolite and urtite keep cropping up in the prose like Wagnerian leitmotive. To appreciate the *Ring*, one has to be able to recognise the leitmotive. The same is true of this book: without a firm grasp of the convoluted terminology of hyper-alkalic volcanism, one is lost.

The first sentence of the first paragraph of the text starts: "The classic igneous intrusions of Fen (Brogger, 1921; Saether, 1957) and Alno (Eckermann, 1948) in Scandinavia, of Magnet Cove, Arkansas (Erickson and Blade, 1963), of Iron Hill, Powderhorn, Colorado . . .". This bleak style is relentlessly preserved throughout the 24 chapters of the book. Nineteen of these are detailed descriptions of individual areas or volcanoes in East Africa written by Le Bas and his colleagues who worked in the area

from 1963 to 1969. Many of these chapters are based on the distilled and condensed Ph.D. theses of research students.

Of most interest to this reviewer was the third chapter, in which Le Bas unravels the nomenclature of the rock suites—this is essential reading and should come before chapter 1—and the last two, which cover magmatic and metasomatic processes and the petrogenesis of the carbonatite nephelinite suite. There are two appendices, containing geochronological and major element geochemical data; there are few trace element data.

Le Bas has produced a thoroughly scholarly work summarising many years of work by him and his colleagues in East Africa, and one which is unequivocally aimed at a specialised readership. The descriptive chapters will undoubtedly provide a valuable source of information to workers studying alkalic volcanism in East Africa and it is clearly useful to have all this data published under one cover. It is a pity, however, that Le Bas did not broaden his scope slightly. There must be many potential readers, not directly involved in the field, who would be glad of an up-to-date and intelligible review of the fascinating petrological problems posed by the carbonatite-nephelinite suites. Only a small proportion of this book is likely to interest them.

Peter Francis

## Molecular trees

*Molecular Anthropology: Genes and Proteins in the Evolutionary Ascent of the Primates.* Edited by M. Goodman, R. E. Tashian and J. H. Tashian. Pp. 466 (Plenum: New York and London, 1977.) \$42.

THIS volume contains 20 chapters, most of which were presented at a symposium in Austria during July 1975. The chapters are grouped under five headings: "Background to Some Key Issues"; "Molecular Evolution as Interpreted by Mathematical Models"; "Primate Phylogeny and the Molecular Clock Controversy"; "Primate Evolution Inferred from Amino Acid Sequence Data"; and "Multigene Families and Genetic Regulation in the Evolution of Man". Forty-nine authors contributed to the compilation, which provides an excellent interplay between scientists in various fields, especially biochemistry, anthropology and genetics.

There is a chapter by E. L. Simons, a palaeontologist, on the fossil record of primate phylogeny, and one on splitting times among hominoids as deduced from the fossil record, by Alan Walker. These provide an interesting and necessary counterpoint for a host of molecular and biochemical phylogenetic trees that are constructed, by authors of other chapters, on the basis of differences between homologous proteins. Various monkeys and other vertebrates have kindly furnished the proteins, especially globins, whose amino acid sequences and immunological cross-relationships are used for the construction of these trees. There is also a short chapter on satellite DNA and ribosomal genes in primates. G. W. Lasker gives us his ideas on what "molecular anthropology" is, with the help of an imaginary dialogue.

The use of comparisons of protein sequences for measuring evolutionary divergence in primates, to which most of this book is devoted, depends on acceptance of the concept of the "molecular evolutionary clock". This concept states that amino acid substitutions in protein molecules take place at an approximately uniform rate during evolution. There is much debate as to how "uniform" this rate is for a given protein. The general consensus is that it runs at different rates at various times.

Most molecular evolutionists use the "clock" to some extent because of its obvious relationship to phylogeny.

In chapter 2, Vogel, Kopun and Rathenberg discuss transitions and transversions in haemoglobin variants. They say that: "CT transitions in the DNA code corresponding to AG transitions in the mRNA code are more frequently observed than would be expected with random substitutions." So-called "CT transitions in the DNA code" are, however, actually base-pair substitutions in which there has been an interchange between an A.T pair and a G.C pair. The decision as to which DNA strand is transcribed depends on which strand contains the binding site for RNA polymerase; and this decision is unaffected by the amino acid composition of the protein that is subsequently synthesised. There is no way of deducing, from an amino acid substitution, which member of the corresponding DNA base-pair underwent the mutation, and which was changed when replication next took place. As the authors correctly note, their compilations are indeed biased, because haemoglobin variants are detected

by electrophoresis, which does not measure changes that are not accompanied by an alteration in charge. In their Table 9, Vogel *et al.* have written alanine codons as the complementary DNA codons. To be consistent with polarity of DNA strands, they should have been written from right to left. Also, one of the codons is wrong.

In Chapter 11, by Matsuda, Table 4 shows the amino acid exchanges and minimum mutation distances in the opposite order from the caption to the table. Chapter 17, by Goodman, presents a lucid account of primate genealogy as deduced from globins and cytochrome *c*.

The book contains extensive compilations of amino acid substitutions in homologous proteins, especially globins, obtained from various primates. It also contains chapters on random and non-random processes in molecular evolution, maximum parsimony, carbonic anhydrase, antibody specificity and gene action.

Thomas H. Jukes

Thomas H. Jukes is Professor of Medical Physics at the University of California at Berkeley.

## Expertise in analytical chemistry

*Analytical Chemistry: Essays in Memory of Anders Ringbom.* Edited by E. Wannien. Pp. xiv+607. (Pergamon, Oxford and New York, 1977.) £27.50.

THIS volume consists of a judicious mixture of authoritative reviews, stimulating and often entertaining essays, and a sprinkling of original papers. The topics are spread across the face of modern analytical chemistry with particular stress on those areas with which the late Professor Anders Ringbom has been most actively associated.

The most homogeneous section is the first, containing some sixteen articles on or related to the stability constants and structures of complexes in solution. They succeed in presenting a very adequate and well-blended picture of the present state of the art, with a significant proportion devoted to the question of mixed complexes which have been so actively investigated in the last decade. In the various reviews, the many technical problems which can so readily disturb or mislead the newcomer to this rather exacting field of study are laid out clearly and amply documented. This section should thus be of particular value to the non-specialist who wishes to update himself, but will I am sure also be read with considerable interest by those with long experience and greater expertise.

The second section is composed of eight articles on various titration procedures and three on colorimetric indicators. This is followed by four articles on aspects of electrochemistry (polarography, electrometric titrations and ion-selective electrodes), five on separation techniques (metal chelates in gas-liquid chromatography, ion-exchangers and extraction), seven on trace analysis (for example, activation, anodic-stripping voltammetry, fluorescence and atomic absorption) and three on kinetic methods of analysis. Finally, there is a miscellaneous section with articles on sampling, the writing of a scientific paper, photoelectron spectroscopy, statistical analysis, capillary electrophoresis, and the history of analytical chemistry.

The 600 closely packed pages provide a curious and varied mine of information and expertise in analytical chemistry, and the list of authors (for example, Kolthoff, Bates, Reilley, Freiser, Margerum, Elving, Laitinen, Anderegg, Beck, Nasanen, Osterberg, Perrin, Pribil, Bjerrum, Irving, Tanaka, Pungor, Almarin, Yatsimirskii, and Flaschka) contains many of the outstanding names in analytical chemistry. This book is a must for the appropriate libraries and should be placed in such a position that chemists, and analytical chemists in particular, are tempted to browse among its pages.

C. S. G. Phillips

C. S. G. Phillips is Lecturer in Inorganic Chemistry at the University of Oxford, UK.

## Problems of desertification

*Desertification: Environmental Degradation in and around Arid Lands.* Edited by Michael H. Glantz. Pp. xiv+346. (Westview: Boulder, Colorado, 1977.) \$20.

THE United Nations Water Conference, held in Argentina in March, 1977, and the United Nations Conference to Combat Desertification, held in Kenya in August, 1977, reflect the worldwide attention now being paid to the destruction of arable or potentially arable land throughout the arid and semi-arid regions of the world. The volume under review comprises a collection of articles by specialists in a range of disciplines which examine and evaluate the social, political, economic, environmental and technical problems related to the causes and effects of desertification. Most of them are concerned, one way or another, with the Sahara and the Sahel savanna of Africa.

In the first of these articles, the editor outlines the approach of the United Nations to "desertification" or, as H. N. Le Houérou prefers to call it, "desertization". Glantz defines this as a global "environmental problem which is primarily national in cause and national in effect". The Sahelian states are among the poorest in the world and, therefore, "in need of financial, technical, moral and other support if they are to have any chance whatsoever to cope effectively with the problems that are linked to desertification within their borders". No-one, however, explains how one should refute the logic of the Sahelian peoples—if, during the last drought, two thirds of their cows died, then, by raising three times as many cattle, the original number might be expected to survive the next drought!

At least half of all the timber cut in the world is used as fuel for cooking or as a source of warmth. Eric P. Eckholm discusses the problem posed by an Indian official: "even if we somehow grow enough food for our people in the year 2,000, how in the world will they cook it?" The suicidal deforestation of Asia, Africa and Latin America will have to be reversed. The problem of ecological deterioration in Niger is discussed by James T. Thomson; that of pastoral development in Somalia by Jeremy Swift. Authors of other chapters include Richard W. Katz, William W. Kellogg, Stephen H. Schneider and Helen Ware. Surprisingly, the Interim Report of the South African Drought Investigation Commission of April, 1922, is reprinted,

without comment, as chapter 10. This historical document shows that neither today's problems, nor their solutions, are new—although the recommendation that jackals should be exterminated might no longer win universal approval.

The review of problems of desert land reclamation in the USSR, by A. G. Babayev, includes an appendix consisting of abstracts of 24 papers published after a symposium held at Ashkhabad, in 1976. Babayev concludes that scientists "must now concentrate on determining the optimum limits of harmonic development of society and nature". "The Communist Party and the Soviet government" seem to have learned that nature may be tamed, but cannot be conquered by man!

## Transport properties of simple liquids

*Classical Kinetic Theory of Fluids.* By P. Résibois and M. De Leener. Pp. xv+412. (Wiley: New York, London and Toronto, 1977.) £22.

"AMONG the many available texts on statistical mechanics, few, if any, give the reader a coherent and sustained introduction to the various methods that have made non-equilibrium statistical mechanics so successful." This quotation from the preface understates the difficulties facing a research worker in the field. If he tries to piece together the original literature, he meets mysterious concepts like "plateau time", "friction constant" and "auto-correlation functions"; and he can have a hard time in deciding whether a theory contains, or does not contain, adjustable constants.

This book contains a connected account of the various approaches to the problem of predicting the transport coefficients of a "simple" liquid. Nearly all the work is concerned with the rigid sphere and  $n$ 'th power repulsion models. Theoretical predictions are compared with "computer experiments" rather than with measurements on the rare gases. This is because of the complicated actual forces between real molecules of "simple" liquids, and also because information such as the time variation of correlation functions can be obtained directly from computer experiments, but can only be inferred indirectly from neutron scattering experiments on real liquids.

The only proper way of dealing with the famous "irreversibility paradox" is to proceed via Liouville's equation. This is done in section C of the book,

A book on deserts seems an unlikely place in which to find a discussion of the world's oceans, but J. Dana Thompson's interesting chapter examines the notion of biological deserts in the ocean, and assesses the limitations of the sea as a biological resource which, however, could be made somewhat more productive by mariculture, the reclamation of polluted areas, harvesting unconventional species, and the abolition of over-fishing. As in the case of all the problems of environmental degradation, we know *what* should be done but not *how* it could be accomplished. The matter is one of individual responsibilities.

**J. L. Cloudsley-Thompson**

*J. L. Cloudsley-Thompson is Professor of Zoology at Birkbeck College, University of London, UK.*

after two introductory sections on stochastic processes and on various forms of the Boltzmann equation. The Boltzmann equation has essentially irreversible solutions, and the central problem is to show that such an equation can be consistently derived from Liouville's equation by proceeding to the thermodynamic limit in a large assembly.

This programme cannot be carried through rigorously for any physically realistic model, but section C makes it clear that most, if not all, of the difficulties of principle have been gradually overcome, and that the remaining difficulties are almost certainly technical. The reader is led through some far from simple work with great clarity, and the style is pleasant and informative. No attempt is made to disguise the difficulties still outstanding—for example, the long term behaviour of the correlation functions and the fact that some treatments give transport coefficients that vary non-analytically with density (or diverge). Paradoxically, such difficulties seem to be particularly severe for two-dimensional assemblies. A final section discusses the, more formal, theory of transport coefficients based on time-dependent correlation functions.

The appearance of the book is most timely. It is splendidly printed and produced and there is a good index and some clear figures. The bibliography is surprisingly short but probably adequate, consisting largely of books and review articles rather than original sources. The authors have certainly achieved the objectives set out in their preface.

**H. N. V. Temperley**

15 December 1977

## The vulnerable side of science

SCIENCE is about people, the ideas they have, how they go about testing these ideas and how they persuade other people to accept them. Science is therefore largely concerned with communication.

Hardly the sort of definition that would get into a dictionary, which is more likely to speak of science as knowledge obtained by observation and experiment, tested, systematised and brought under general principles. Organised knowledge doesn't at first sound a very personalised affair—it has too obvious associations with the certainties of the periodic table and suchlike, or the neatness of textbooks. Yet every thinking scientist knows that just as 'coal' means a neatly stacked cellar of the stuff to the householder, but something highly personal, both friend and enemy, to the miner at the coalface, so 'science' is not only a neatly stacked cellar but also a complex and messy affair, a very human business with all its successes and failures, argument and consensus. This side of science is relatively poorly understood by the non-scientist. And even scientists themselves sometimes forget it when constrained to write short scientific papers or deliver ten-minute talks in which there is only room for the reporting of success, not the detailing of blind alleys, tortuous discussions, uncomprehending referees.

Because science is so much dependent on free and easy communication amongst its practitioners, anyone who interrupts the channels of communication used by scientists is capable of doing immediate and serious damage not just to those closely involved, but also to the advancement of science. Neutralise a fertile thinker in informal contact with tens, even hundreds of other scientists, and no-one else will be able to fulfil anything like the same role. And neutralising doesn't involve anything as vulgar as demolishing a particle accelerator or breaking up a laboratory. It simply means making one person difficult to get hold of and denying that person the normal means of communicating with the outside world. There are plenty of ways, both subtle and unsubtle, of achieving this, and the demonology is not restricted to governments.

It is, thus, encouraging that 1977 has seen a growing awareness by scientists of the importance of human rights issues, and a gradual realisation that talk of freedom of expression and interchange of ideas in high-flown and little-read international documents need not necessarily be meaningless but could be a lifeline, however fragile, to a beleaguered scientist. The report early in the year by the Council for Science and Society on scholarly freedom and human rights must be reckoned a major milestone in providing scientists with the necessary theoretical support to their practical actions and now, with the Belgrade review of the 1975 Helsinki European security conference drawing to a close, it is reasonable to wonder whether there are any signs that scientists are gaining or losing in their quest for the right to express themselves and communicate with each other.

Obviously there is no measure of such a complicated thing as freedom for scientists to be part of a global community, but even so there are few grounds for believing that things are getting better. Nor is tampering with scientists, and therefore with science, the preserve of any one power bloc or group of nations; there is gloomy news from many parts of the world. And lest it be thought that Western countries can be smug and self-satisfied in these matters, it should also be said that commercial secrecy and national security are often the justification by which *bona fide* scientists are gradually worn down into conformists, afraid to speak out on matters where they have high technical competence.

On the other hand there are favourable signs. Within the next few months it is expected that ICSU's Committee for Safeguards of the Pursuit of Science will come forward with some new proposals, and it is hoped that these will encourage the establishment of some centre to which scientists may turn for assistance or to which malpractices may be reported.

1978 marks the thirtieth anniversary of the adoption by the United Nations of the Universal Declaration of Human Rights. It could well be the year in which the simple, yet very vulnerable needs of the scientist at last get a heavyweight defender. □

# Stalin's scientific deputy addresses dissident meeting

THE inclusion of a symposium on scientific research in the Venice Biennale on culture has been described as an "act of considerable courage". Since the general theme of the 1977 Biennale was "cultural dissidence" it was hardly surprising that the round table on scientific freedom should include many who have shown considerable physical and moral courage in the defence of academic liberty. Voronel, Turchin, Plyushch, Dediu, Zhores Medvedev, the Papiashvilis, the Chudovskii brothers—the list of speakers reads almost like a role of honour of the dissident movement in science. Moral courage of no less an order, however, was shown by Dr Arnost Kolman, who, to an audience of active campaigners for scientific liberty, delivered a paper that, under the unassuming title of "The Adventure of Cybernetics in the USSR" described his part in Stalin's campaign to destroy free scientific progress, and replace it by a special party-orientated science.

Dr Kolman, at 85, is a living link with Lenin and the early days of Soviet power. His personal philosophy still remains Marxism, which he sees as having become under Stalin "the obedient servant-girl of political power". His picture of his destruction of science during those years is a horrifying one, since, he explained, it was carried out not by cynical careerists, but by people acting in good faith, but incompetent in the field in question.

Thus he, himself, trained in maths and physics, campaigned during those years against the prevailing philosophy, in defence of relativity, quantum physics, and mathematical logic. In life sciences, however, and particularly in genetics, he was fully prepared to accept the party dogma which pronounced genetics a pseudo-science. He

described how the editorial board of the philosophical magazine, *Under the Banner of Marxism*, of which he was a member, were given a mere three months to familiarise themselves with the theory and problems of heredity—and then to take up the battle against "mendelov-morganism", championing the "innovatory ideas" of Lysenko.

Kolman's paper was not only absorbing—as the *mea culpa* of a notable figure has always been fascinating from the days of Augustine of Hippo onwards—it also set the tone for the whole symposium by stressing the danger inherent on state interference in science. Zhores Medvedev gave a most lucid account of Soviet science policy during the last 60 years, several papers dealt with more recent events in Czechoslovakia (Frantisek Janouch, L. Durovic, and O. Poupa) and in Romania (Mihai Dediu). Kolman's revelations showed, however, that such interference need not necessarily be effected by bureaucrats or party apparatchiki, but by persons who genuinely believe that in doing so they are serving their country and the cause of scientific progress.

Against this background the more theoretical papers took on a significance transcending the current situation in the USSR and Eastern Europe. John Ziman's masterly exposition of the ethical principles underlined the concept of scientific liberty. Giorgio Bert on "Medical Science as an Ideology", Mark Popovskii on "Controlled Science", and Valentin Turchin's enquiry into the correlation between scientific training and involvement in human rights, all raised fundamental problems of the moral responsibility of scientists everywhere.

Likewise, in the special session on the political misuse of psychiatry, Dr Sidney Bloch noted that the revelation

during the last few years of Soviet malpractices had caused many psychiatrists throughout the world to reassess their personal ethical standards.

A number of speakers, in particular Giacomo Morpurgo, stressed the need for rapid and accurate dissemination of information of scientists subject to restriction and deprivation of academic liberty. The work of Amnesty International did not go unnoticed; but it was stressed that Amnesty campaigns only for those actually in prison. Owing to the rapid advance of science, exclusion from professional activity for more than a few months may produce irreversible academic "death". Hence the intervention of the world scientific community at the initial stages of academic restriction is a matter of considerable importance. A prime example of what can be achieved was the worldwide outcry against the campaign to expel Sakharov from the Soviet Academy of Sciences in 1973. Reports of specific efforts were received from Jeremy Stone (Federation of American Scientists), Tania Mathon (Solidarity Committee of French Scientists) and Goran Borg (Swedish Committee for the Freedom of Science).

Repeatedly throughout the symposium it was stressed that, although the theme of this particular meeting was repression and dissent in Europe, the problem of scientific liberty is indivisible and transcends all national frontiers. It is an integral part of the world-wide problem of human rights: if the cases of scientists command particular attention, it is because in this post-atomic age, the outcome of state misuse of science and technology can threaten the future of the entire world. The ethical responsibilities of scientists to their profession and to their colleagues are accordingly proportionally great.

Vera Rich

Arnost Kolman: a living link with the early days of Soviet power

## Sakharov warns of subtle pressure

The Soviet physicist Andrei Sakharov sent a personal message to last week's Venice Biennale. The following is an extract from his message:

"Liberty of opinion and exchange of information are of great importance throughout the world. . . . The new climate of international relations, called detente, has led to even more complex and varied links and communications, hence not only have the possibilities of positive influences been increased, but also the danger of the diffusion of more negative characteristics. This has increased mutual responsibility. . . . I consider the initiative of the Biennale to be very important, dedicated as it is to the problem of dissidents and non-official

creativity in the socialist countries. I myself belong to this scientific sector in which the ideological pressure of the state is nowadays not expressed entirely explicitly. . . . The epoch of the ideological struggle against the theory of relativity, quantum mechanics and cybernetics—the most shameful page in Soviet science . . . fortunately belongs to the past. . . . (Now) perhaps the most important thing is the humiliating position of the intelligentsia in the whole country, which is shown particularly in the inadmissible misery of the two most wide-spread intellectual professions—doctors and teachers—and in the total subjection of the intelligentsia to bureaucratic party control".

## New defence science chief offers cash to UK universities

UNIVERSITY and polytechnic scientists should become more closely involved in helping to determine strategies for defence research, according to Professor Ron Mason, the newly-appointed chief scientist to the UK Ministry of Defence.

Even five years ago, such a statement would have generated hostility from university colleagues and students alike. Both were concerned—for different reasons—with intrusions into the “purity” of research. Yet when Professor Mason’s appointment was announced at a meeting last week at the University of Sussex, where he has been professor of chemistry since 1971, even a student representative present greeted it, he says, with applause.

With the continued squeeze on university funding, and a growing acceptance of department-sponsored research, Professor Mason claims that there now exists a “more relaxed view” in universities about accepting military funds than a few years ago.

As chief scientific adviser—considered by many to be the highest position that any British scientist can hold in government—one of his main tasks will be to act as an interface with the scientific community. And the new atmosphere should, he feels, make this easier to achieve.

“One of the first things I want to engage in is a discussion on the relative balance of intermural and extramural research, and personally I would like to see a substantial increase, so broadening the base of expertise and advice,” Professor Mason said this week.

He emphatically rejects the notion canvassed by the Campaign for Nuclear Disarmament and others that university scientists should refuse to carry out military research on principle. A scientist’s responsibility should be to produce first-rate research in pursuit of aims determined by the conventional political processes.

“The proviso, of course, is that all research carried out on Ministry of Defence contracts should ultimately be publishable in the normal way; as a university man, I would be worried if an academic institution accepted any restrictions on publication.” Professor Mason has himself in the past received funds from the Microbiological Research Establishment at Porton Down in support of certain aspects of his work on ion transportation across cell

Ron Mason: “a more relaxed view” on military research

membranes, and feels no qualms at having done so.

“Another reason for wanting closer contact with scientists in universities and polytechnics is to open up discussions about long-term trends in defence research. And since these involve a mix of the scientific and technological with economic and political factors, a broad interdisciplinary discussion of objectives is required for which the ministry research establishments are not equipped.”

Professor Mason is no stranger to the world of science and technology policy, having been a member of the Science Research Council from 1971 to 1975, and chairman of its science committee for three years. He has also been a member of the requirements board of the Department of Industry since 1973.

One area in need of investigation in his new job is, he says, the systematic under-recruitment of scientists and engineers by the Ministry of Defence that has taken place in recent years.

“Whether a reluctance to take up a career in military research is due to the unattractiveness of Civil Service salaries in general, or of this type of work in particular, is at present unclear. But it might be a good idea for me to go out to talk to people in universities to help find the reasons for this situation.”

Professor Mason admits to being slightly “bewildered and overwhelmed” by the scope of his new job, which he takes up on 1 March, 1978 on a three-year secondment from the university.

He is convinced that the key to its success, at least in developing links between the scientific community and the defence establishment, lies in opening up discussion about military research; but whether closer liaison is acceptable to either party remains to be seen.

David Dickson

## Soviet beams over Sweden?

Is the Soviet Union developing a charged-particle anti-satellite weapon? Reports earlier this year listed evidence that tests of such a weapon had been carried out at a research facility near the Soviet city of Semipalatinsk, and described the debate raging between the US Air Force, convinced that the tests were being carried out, and the more skeptical CIA. A Swedish scientist has now published some findings that will add to the speculation.

Dr Lars Erik de Geer of the National Defence Research Institute detected traces of radionuclides neptunium-239 and molybdenum-99 in the atmosphere over southern Sweden on five occasions during the first half of 1976. The same atmospheric samples also contained small amounts of fission products iodine-131 and barium-140. On the first two occasions—in late February, and March—the prevailing winds had been from the east during each period of three days when the nuclides had arrived. On the other three occasions—in April, May and June—the winds had blown from the east on at least two days in each week during which the nuclides came. Dr de Geer thus postulates that “the material arrived in Sweden by way of southern Finland or western USSR and the Baltic Sea”.

What could have caused such activity? The short answer is: no known source. The amounts of neptunium and molybdenum detected are compatible with the ratios found in debris that circulates for a few weeks after the explosion of a nuclear bomb. But, as Dr de Geer points out, if these nuclides resulted from some fission process, it is strange that other short-lived fission products (such as tellurium-132) were not also detected. Neither is the composition of the samples consistent with discharge from an ordinary nuclear power reactor. He wonders whether some laboratory experiment involving fresh fission products could have been responsible; but a check on research laboratories in Sweden, Denmark and Finland showed that no such work was in progress during the period in question. The

most exotic explanation—that the nuclides were produced by charged-particle beam experiments in the Soviet Union—seems to fit in that the observations were made at the same time as the experiments at Semipalatinsk were reportedly started. According to meteorological trajectories, however, nuclides from this area of the USSR could have been carried to southern Sweden in March, April and May, but probably not in February or July. This means that, although the nuclides detected in February were deposited by an easterly wind, they probably came from a source other than Semipalatinsk. Given the nuclides' short half-lives (ranging from 2.35 days for neptunium-239 to 12.79 days for barium-140), and the distance from Semipalatinsk to Sweden (about 4,000 km), the winds carrying the nuclides would have to have been strong. Although meteorological data suggests that the winds probably would have been strong enough, sufficient doubt remains for Dr de Geer to cite this as a factor against the Soviet source.

Dr Kay Edvarson, of the National Institute for Radiation Protection, comments that it is impossible to pinpoint a unique source for such activity. "We have fairly extensive surveys made now on releases from power reactors, and Dr de Geer's findings don't really fit any reactor types known to us. The National Defence Research Institute quite often detects some radioactivity which can not have come from a nuclear test. These samples are generally assumed to have come from small, localised sources such as a hospital. But it is impossible that the sort of activity Dr de Geer detected can have come from such a source. On three occasions the nuclides were detected at several sampling stations in southern Sweden, so it's highly improbable that the source was localised. It has to be reasonably far away, and strong. If it had been a strong source somewhere in the Nordic countries or West Germany, we would have heard about it." He points out that the probability of detecting the sorts of samples now under discussion is small.

"They would be masked by fairly fresh debris from a nuclear test", he says, "and the release time has to coincide with the wind pattern".

Dr Bhupendra Jasani, of the Stockholm International Peace Research Institute (SIPRI), says it is difficult to think of any sources other than those mentioned by Dr de Geer which might have caused the activity. "I am very skeptical of those who claim that the Russians have a charged-particle beam weapon in operation", he says. "However, the Soviets are pioneers in accelerator physics and accelerators, and they could well be working on such weapons—just as the Americans may be." Dr de Geer's report, published in *Science*, quickly drew a statement from the Pentagon questioning the hypothesis of the Soviet source. But, as Dr de Geer points out, "I am not saying that the nuclides came from charged-particle beam weapon tests in the USSR. It is simply that, as no other source seems to fit, the possibility that they did has to be considered."

Wendy Barnaby

## Sweden follows US example on aerosols

SWEDEN is to become the first country in Europe to ban the manufacture and use of chlorofluorocarbon (CFC) propellant gases in aerosol sprays.

The ban, which will take effect in 1979, reflects public concern at the possibility that such gases may deplete the stratospheric ozone layer, hence potentially reducing the atmosphere's ability to screen ultra-violet rays, and leading to an increase in skin cancer.

In the US, fears that the extensive use of CFC gases could cause a decrease of ozone of up to 14% over a period of 100 years have already led to a similar ban, the result of a joint decision by the Food and Drug Association, the Environmental Protection Agency, and the Consumer Product Safety Committee.

Sweden is the first country in Europe to follow the American example. The Swedish Government's action is based on a recommendation of its Products Control Board that a licensing system should be introduced for aerosols, and that such licences be withheld from most aerosols using CFC gases.

The manufacture and import of such sprays—excluding certain products required for special uses such as medicine—will be banned from the beginning of January 1979, and their sale from the following June.

The move has already brought reaction from a number of Sweden's trading partners in the European Free Trade Association (EFTA), concerned at the economic impact it may have. Finland,

for example, which exports many aerosols to Sweden, has asked Stockholm either to withdraw the ban, or to extend the timescale considerably.

The Finnish request is based on the position held by the majority of Euro-

"It's an aerosol for getting rid of Finnish aerosol salesmen"

pean countries that although CFC aerosols represent a theoretical danger to the ozone layer, no substantial evidence has yet been produced to indicate that any significant depletion of ozone does indeed take place.

Widespread public controversy has surrounded the issue since the possibility of such depletion was raised by

Rowland and Molina in 1974. It is this concern that has led to the current ban in the US, where many manufacturers are turning to the use of hydrocarbon gases as an alternative.

No theoretical model of the chemical interaction between ozone and CFCs in the atmosphere, however, has yet produced an adequate representation of what actually happens. In particular, most models rely on a one-dimensional interaction, and are hence unable to take into account the full three-dimensional movement in the stratosphere.

In view of the scientific uncertainties, countries such as Britain, Germany and France have decided that more research is needed before a decision about whether or not to ban CFC aerosols. The EEC has recommended that a review of the situation be made in the second half of 1978, and has also commissioned the UK-based consultants METRA to carry out an economic impact study on the effects of a ban.

The Swedish government has therefore decided to break ranks with other European countries, and in particular its Scandinavian neighbours. However the decision is likely to be welcomed in the US, where FDA commissioner Donald Kennedy said earlier this year that since the threat of ozone depletion was a global problem, he hoped other countries would follow suit.

An official of the Swedish Department of Industry said in Stockholm last week. "The Swedish philosophy is that this will take a long time, and someone has to take the lead."

## Bangladesh reviews science policy

MODERN science and technology was introduced to the Indian sub-continent by the British during the late 19th century. It developed in only a few areas of present day India, no significant development taking place in those areas which now make up Bangladesh and Pakistan. A national policy for science and technology development there was initiated as late as the 1960s. Planning and executive agencies were subsequently formed and some institutions for scientific and technological education and for research and development were established. Over the last ten to fifteen years an indigenous scientific and technological infra-structure has begun to be built up in Bangladesh.

The need for an integrated science and technology policy in Bangladesh has led to the formation of the National Council for Science and Technology (NCST) to advise the government on formulating policy, and planning, coordinating and evaluating science and technology development. In concrete terms the NCST determines national objectives, formulates strategy and identifies areas where science and technology can contribute to national development. The talks also include coordinating and evaluating scientific and technological programmes in various sectors, and the development and motivation of scientific and technical manpower.

The government of Bangladesh has now undertaken economic development programmes to raise the standard of living of the people and improve socio-economic conditions. Implementation of these programmes needs specific technological capabilities. Any assessment of future possibilities and formulation of appropriate development strategies must be based on an analysis of national strength and weaknesses which should take into account the potential contribution that science and technology can offer. Science and technology policy for both short and long term strategies, thus, constitutes an integral part of the country's overall development plan.

With a view to planning and programming scientific and technological developments effectively, the NCST has undertaken to establish a data base on manpower, and the funding, management and facilities for the existing scientific and technological infrastructure. This would involve surveying existing scientific and technological personnel and stock taking of the research institutes, laboratories, workshops and supporting facilities. The current programmes in these institu-

tions are to be reviewed and plans for the development of existing scientific and technological institutions are to be made on the basis of the results of these surveys and reviews. Further, NCST intends to undertake studies and make recommendations on the organisation and modes of financing of the research councils, institutes and other supporting facilities.

On the development of human resources in science and technology in Bangladesh, NCST proposes to review the existing education and training programme and suggests appropriate measures for their expansion and improvement. Recruitment and promotion rules for scientific and technical personnel with appropriate measures for proper incentive and motivation. The government has already instituted a fellowship programme for science, engineering, medical and agricultural graduates who cannot find suitable employment inside the country or experts working abroad but interested

in joining the institutions of Bangladesh.

NCST intends to undertake a comprehensive scheme for preparation and production of science and technology text books in Bengali and reference books in both Bengali and English up to the highest level of education and to advise the government on its phased implementation. Popularising science and technology and disseminating scientific knowledge among the public, particularly on the human implications and social impacts of science and technology will be one aim. In the long term these studies should lead the government and other concerned agencies to formulate the philosophy, guidelines and workplan for a course of action.

Bangladeshi science and technology policy also envisages longterm studies on the development of scientific and technological potential, appropriate or alternate technologies, policy guidelines for international and regional cooperation and promotion of associations, academic and professional bodies and human rights for scientists.

## FAO conference embraces third world

WHEN, in January 1976, Edouard Saouma, a Lebanese Christian, took over as Director General of the Food and Agriculture Organisation (FAO), there was a good deal of headshaking among the old hands in international agriculture, and when he announced his policy for improving the efficacy of the organisation, there was even more heart-searching among the senior staff. His policy was aimed specifically at more direct contact with ministries of agriculture and development in the Third World countries.

The FAO biennial Conference, which ended early in December at the headquarters in Rome, must have given Saouma a good deal of satisfaction. After two years of his regime, government after government expressed approval and encouragement for the policy at which many of their representatives had looked askance early in 1976. Nor did this approval come only from the Third World countries towards whom the new policy has been especially directed.

The most far-reaching of Saouma's ideas has been the Technical Cooperation Programme. Seen initially by many as a duplication of effort with the UN Development Programme (UNDP) this has now proved its ability to provide small-scale assistance for specific projects at very short notice—something the cumbersome machinery of UNDP has never been able to provide. In its first year, 190 projects have been approved under this programme. The success of

this scheme certainly owes a good deal to another innovation, much criticised when announced: the appointment of FAO representatives to certain countries, again in order to provide direct and rapid contact in critical areas.

Two other activities came in for special approval from many delegates in Rome. One was the Seed Improvement and Development Programme, fundamental to increased production in the developing countries. The other is the campaign against post-harvest food losses—something for which every FAO Conference has asked since the organisation came into being. Since it is estimated that cutting such losses by half could save up to \$7,500 million a year in the foreign exchange for the developing countries, the amount allotted for initiating this campaign, a mere \$10,000, seems modest indeed. It is hoped to double this with external contributions.

Referring to the 1979 World Conference on Agrarian Reform and Rural Development, Saouma said that he wishes to "avoid confrontation, rhetoric and confusion"; many observers must have noted that he certainly managed this at his own Conference, at a time when politicising and backbiting have come to be a normal part of such major international meetings. This is perhaps another good augury for his ability to control the spending of the \$237,377,000 he is asking for his regular budget for the biennium 1978-79.

**Peter Collins**

## Australian election leaves uranium issue confused

**L**AST weeks' general election in Australia scarcely changed the massive majority held by the Liberal and National Country Party coalition government. Nor has it changed the odds on whether or when Australia is to become a major exporter of uranium.

At first sight this observation may seem paradoxical—even perverse. Surely such a total victory must have fortified Mr Fraser and his government in their confrontation with the opponents of uranium mining? This certainly seemed to be the view of the uranium mining companies expressed through their lobby organisation, the Australian Uranium Producer's Forum. Within hours of the election result being known the forum's chairman declared that the Fraser government now had a mandate for its uranium export policy. Unfortunately even if one accepts the dubious mandate the mining companies' view is without foundation.

While the government parties polled about 48% of the national vote, the combined vote of the two main parties advocating a moratorium on uranium mining, the Australian Labor Party and the Australian Democrats, was almost 50%. Furthermore, it would be hard to argue that the uranium issue was at the forefront of most voters' minds as they went to the polls. Although it had been seen, before the event, as a crucial issue in a December general election, in the event uranium received relatively little attention during the campaign. The government parties, in particular, seemed to go almost out of their way to avoid discussing uranium and nuclear power. In an opinion poll conducted eight days before the election, one of the more respected polling organisations found that only 5% of voters considered uranium export to be the most important election issue. Thus the election result is in no sense a positive endorsement by the majority of Australians of the government's policy on uranium.

### Government undeterred

This fact is unlikely to deter the government from attempting to claim a mandate for its policy. And the election result is certain to increase its confidence in seeking a confrontation with those who oppose it, which means, principally, individual unions or the trade union movement as a whole. There has been considerable speculation about when and how such a confrontation may occur. In the transport

of yellowcake, unions have already taken industrial action on uranium.

The most crucial of the unions are almost certainly those in the building and engineering industries, whose members will have to be involved in constructing the mine and mill. These unions are mostly large, well organised, and strongly opposed to the mining and export of uranium. They seem certain to be in the vanguard of any confrontation with the government. While it is obvious that a great many factors will determine the outcome of a confrontation, should it occur, the support which the unions receive from the labour movement as a whole and from the general community will clearly be of great political importance.

There is now a large and articulate opposition to uranium export, co-ordinated nationally through the movement against uranium mining. While not yet as large as the movement opposing the Vietnam war was at its peak, the opposition to uranium mining appears to be both better organised and politically more sophisticated.

Up till now Mr Fraser has treated the uranium issue with great circumspection. His failure to use it as an election issue could be taken to indicate uncertainty about the popularity of his policy. In explaining the policy, he emphasised that following the reports of the Ranger Uranium Environmental Inquiry (otherwise known as the Fox reports) he has demonstrated in both word and action the importance he attached to improving safeguards against nuclear weapons proliferation. All these moves may have been effective in reassuring uncommitted opinion on the uranium issue; though if Mr Fraser was hoping that he would also placate his opponents, he must have been disappointed.

However, there are now signs that the government is being less cautious in pursuing its uranium export objectives. For example, it has so far failed to provide the necessary finance and administrative support for the team appointed to carry out environmental research and supervision in the Alligator Rivers region of the Northern Territory, where the major uranium deposits are located. While the hold-up may simply be the result of bureaucratic inertia or parliamentary delay, the opponents of uranium mining are inclined to see it as presaging the breaking of promises on environmental protection.

Much more important, at least in the international context, was the state-

ment in the last week of the election campaign by the Deputy Prime Minister and Minister for National Resources, responsible for uranium in Mr Fraser's pre-election government, Mr Anthony. He announced that the government was reconsidering its policy of prohibiting the reprocessing of spent reactor fuel made from Australian uranium, and does not wish to rule out reprocessing by 'acceptable' countries. This change in policy would make it difficult for the government to continue to argue that by exporting uranium it was furthering President Carter's policy of preventing reprocessing and the plutonium economy by providing ready access to supplies of nuclear fuel.

Mr Anthony has consistently been far more blunt than Mr Fraser in his support for uranium mining and his statement may not have the support of Mr Fraser. In the immediate aftermath of the election it is not certain that Mr Anthony will retain responsibility for uranium development in Mr Fraser's new government. However, his statement undoubtedly reflects the problem the government is having with its policy on proliferation. President Carter's policy on nuclear fuel reprocessing is clearly in some difficulty, and may be abandoned. More important from the Australian government's point of view will be the firm commitment to reprocessing by its major potential uranium customers: Japan, West Germany, and the UK.

### Economic question

Finally, there is the question of the economics of uranium mining. Canadian officials involved in making decisions on the development of the new uranium prospects in Saskatchewan recently expressed amazement at what they considered to be highly optimistic expectations of both sales volume and price of uranium held by the Australian government and mining companies. The uranium debate in Australia does not so far appear to have comprehended the considerable down-turn in uranium market prospects over the next ten years or so, which has taken place recently. When the Australian people realise that an immediate start to uranium mining may not bring the great economic benefits they have been led to expect, they may be less willing to support the government in any confrontation that may occur. It is noteworthy that one of the few seats to record a significant swing against the government was Northern Territory, where much publicity has been given to the possible economic benefits of uranium mining. There is still a very long way to go before Australia becomes a major uranium producer.

## Letter from Argentina

SIR,—I welcome the concern Louise Harel, Jose Uriel and Jean-Claude Salomon show to my countrymen (3 November, page 8) by inviting professionals not to participate in the twelfth International Congress of Cancerology to be held in Buenos Aires, in October 1978.

However, while I believe that sincere international solidarity can be of great help in the fight for universal human rights, and while I welcome the writers' desire to see democracy upheld, I believe their proposal in this case is misguided.

Many countries are suffering from terrorism. In Argentina scientists, professional people, students, workers, policemen and the military, priests, women and children have been affected. It is true that there is a long list of people who have disappeared or been kidnapped and that some have been forced to emigrate by intimidating threats and torture. But action is also being taken against all kinds of terrorism. President Videla has repeatedly declared that the state is the only force charged with the security of people and that any illegal repression will be severely punished. He has also expressed the need for exchange of opinions if Argentina is to be based on a renewed, stable and progressive democracy.

These concepts are shared by the Permanent Assembly for Human Rights and by the Argentine League for the Rights of Man, both functioning legally. Political personalities, cultural and scientific representatives, as well as others from all branches of activities, publicly condemn the terrorist violence and call for an end to persecution and arbitrary repression.

But is a decision to boycott the International Congress an appropriate way of expressing solidarity? Is it in effective way of helping us reach a democratic goal? I think not. One of the objectives of terrorism is to disorganise the life of a country, to create a climate of intimidation and to isolate the nation from the international community. A boycott of the Conference would contribute to this isolation and would favour the plans of terrorists to promote chaos. The fight against terrorism should stem from the organised way of life of the country itself, which will break up antisocial manifestations. The government has assumed this

responsibility by proclaiming its monopoly of repressive actions against terrorism. It is also the responsibility of the democratic forces which speak out for the right to work in peace and liberty. This is what scientists, professional people, workers and their institutions and associations are doing. All these activities are proceeding in spite of economic restrictions and social violence and they should be supported.

No matter how great the concern of our colleagues abroad, Argentinians are far more concerned about showing support for security and peace. It is precisely to show solidarity with our efforts that foreign scientists should come to our country, should acquaint themselves with our complex reality, should make their contributions towards the fight against cancer and should acquaint themselves with the Argentinian work on the subject.

I am making this appeal as a scientist who has been dismissed from his position in the National Council for Scientific and Technical Research (CONICET), for "service reasons", without any justification. I have not emigrated, neither have most of those affected. I have asked for reconsideration and I will continue my fight for justice. I am going to participate in the International Congress of Cancerology with my modest contribution under such difficult circumstances. I am confident that the patriotic forces of our country, both military and civil, will find a way of effectively restoring democracy. All honest Argentinians are striving for this end. The presence of foreign scientists at the Congress will be an expression of respect and solidarity with our human and scientific endeavour when we need it most.

EMANUEL LEVIN

Buenos Aires, Argentina

## Go to Argentina

SIR,—Once more the European scientific community is threatening to boycott the scientists of a specific country because of the type of government they have ("Petition for Argentinian scientists", 3 November, page 8). I think this is unfair to the great majority of scientists and students of the particular country. I would like to comment on this problem by taking the example of Chile, my native country.

As a small country with a low population, mainly supported economically by copper exportation, Chile used

to have the reputation of being an example of democracy in a continent where, together with two or three other countries, it was the exception. Its universities had excellent research groups in many disciplines able to compete with scientists from much richer countries.

All this was jeopardised by the 1973 military "putsch"; the research effort was severely affected but not killed (see "Science in Chile since Allende", *Nature* **265**, 486, 1977). Many Chilean scientists left the country, some because of direct persecution, others because of political ideas or moral convictions. The first of these groups was composed of scientists who had key positions during the 1970-73 period, or who were considered to be important by the "new lords". Many of these people were imprisoned and then went abroad through embassies. In the second group are many scientists who had already been abroad and for whom the possibilities of obtaining good positions in the USA and Europe were favourable.

Some university departments had to close down because all the teaching staff had left. This was the case for disciplines like physics and mathematics. In the field of biochemistry, however, an important number stayed, although many left. Who are these women and men who did not leave?

Are they all fascists as is generally assumed, mainly in Europe? One thing is clear to me: the longer they remain isolated from the rest of the world, the more likely it is that they will become convinced by the government of the so-called "general Marxist confabulation against Chile". There may be a small fraction of native academics that is sympathetic to and even enthusiastic about the "junta", but most of the Chilean scientific community is made up of convinced democrats who have supported leftist or left of centre political positions. For professional or familial reasons they have stayed in Chile.

What happens when an invitation or the opportunity to visit Chile is open to a foreign scientist? Immediately thousands of voices full of fury are raised to protest against such support of the authoritarian regime. This is extremely evident among European unions or intellectuals. Of course, other annual exchange programmes organised by certain European governments with other dictatorship-ruled countries do not raise such a reaction.

The attempt to isolate Chile reminds me of a similar attempt to isolate Brazil a few years ago. Although the Brazilian government is still very authoritarian, scandals are no longer caused when foreign scientists are invited to Brazil. Moreover, the great majority of the Brazilian scientists are opposed to the military government (although many of them returned to Brazil after the military took over, because of very important salary rises).

The main victims of this isolation, at least in the case of Chile, were the common people and more specifically scientists and students. The Chilean government, less stupid than generally thought, has used the argument of "all against us" as a powerful nationalistic tool. It seems aberrant to me that while scientists from all over the world are being persuaded from going to Chile, a superpower, which originated and supported the isolation campaign, is engaged in an exchange of political prisoners with the Chilean government, giving a tremendous popular credit to the military junta inside the country. A visit of all Nobel laureates to Chile, would not strengthen the military as the exchange of prisoners did.

Attending an international scientific meeting or visiting a Chilean or Argentinian university is not synonymous with supporting the military government of these countries. On the contrary it is a unique opportunity to contact scientists and students and to encourage and help them to overcome the scientific and moral isolation they suffer.

We have to remember the case of Spain, a country which until a few years ago had the same type of government as Chile and Brazil now have. As long as it was isolated from the world no hope of ending the dictatorship existed. As more and more foreigners entered the country, an irreversible flow towards democracy started.

No tourist boom can be expected in Chile or Argentina, but scientists and academics passing through can be an indispensable link with students and scientists. Without this bond, they may be convinced by the chauvinistic arguments used by the government each time a world campaign is organised against it.

This is a plea not to support the South American dictatorships or to ease the criticisms against them but to maintain a link between their scientific communities and the rest of the world. This may be the unique possibility of keeping alive the result of years of effort, and the only hope of evolution towards the revival of democracy in these countries.

**Competition 15** asked for an appropriate quote for our front cover. A good varied entry with an honourable mention to D. Irwin (Boston) for "Pereant qui ante nos nostra dixerunt" (May those perish who have said our things before us). But £10 goes to the Mammalian Development Unit, University College, London

## Technik or technics

SIR,—On most topics, I would not set out to disagree with those who write to support me. However the question is too important to let go: it concerns the separateness of the German-language notion of a third culture of *Technik*.

Rey and I (1 September, page 2) argued that the idea of *Technik* represents a missing concept in English, whereas Cavalier-Smith (20 October, page 646) would like us to follow Lewis Mumford instead and revive the English word "technics". We avoided "technics" because Mumford got things very wrong in the book referred to, *Technics and Civilisation*.

Notably he argued for a distinction between the "neotechnics" of the age since about 1880 or so, and the "paleotechnics" which went before. Of the period just before neotechnics, he wrote that its inventions "came into existence, for the most part, without its [science's] direct aid"; whereas later in the "neotechnic phase, the main initiative comes, not from the ingenious inventor, but from the scientist who establishes the general law: the invention is a derivative product".

Detailed investigation does not support this viewpoint, or the distinction between ages of manufacture on which Mumford's thesis is founded; science has always influenced manufacture, but never controlled it. Neither does detailed investigation support the viewpoint of R. J. Forbes, the author of *Man the Maker* (1950, Shuman), another hero of the historians of "technology". He writes his subject up, most misleadingly, as an account of the exploits of "applied science" through the "conquest of nature". A reliable book of the influence of *Technik* on the culture has yet to be written.

I am absolutely at one with Cavalier-Smith, however, that there is only harm to be done to science in the long term, through a blurring of the distinction between science and the technical

who communally turned up: "Is this," I cried, "the end of prayer and preaching? Then down with pulpit, down with priest, and give us Nature's teaching!" (Whittier)

**Competition 16.** To the uninitiated, many scientific pictures are ambiguous: a section through a cell could equally be a slice of a lunar rock. Readers are invited to give a misleading caption to any picture that has appeared in, or on the cover of, a recent *Nature*. £10 to the winner. functions of manufacture. One vehicle for this harm has been the ghastly construction called "technology"; the only "-ology" in history to make useful, bulky artifacts as a primary output, a word which outsiders to manufacturing use when they want to hide their ignorance of it.

## Sunflower's siesta

SIR,—Observations on the sunflower's night life (8 September, page 102) prompt me to put on record a piece of its daylight behaviour which I have never seen described before. In Turkey, in July this year, I consistently saw that at 1 pm on bright days the flowers all faced the sun but by 2.30 pm all heads had turned away and faced north. At about 5 pm they again began to face the evening sun and ended the day facing west.

Perhaps even the sunflower finds the Turkish afternoon summer sun a bit hot and has a thermal switch overriding the sun-tracking mechanism, so that it can have a siesta. Is the siesta phenomenon unusual, or do sunflowers always behave like this in hotter climates?

## Immune surveillance revisited

from R. W. Baldwin

THE immune surveillance theory as developed by Burnet (*Immunological Surveillance*, Pergamon Press, Oxford, 1970) proposes that a central role of the immune response is to provide a natural defence against cancer and this was later developed to emphasise the importance of thymus-dependent lymphocytes. It was, therefore, more than a little disconcerting to find that congenitally athymic (nude) mice do not have an increased incidence of spontaneous cancers and they are no more susceptible than conventional mice to chemical carcinogens (reviewed by Stutman, *Adv. Cancer Res.* **22**, 261; 1975).

It is axiomatic, however, that nothing in tumour immunology is simple and it has recently been proposed that whereas T lymphocytes may be an important component of the responses induced by immunological manipulations, such as immunotherapy, they may not have a central role in more natural conditions such as those involved in recognising clones of transformed cells. Instead, attention is being focused on so-called 'natural killer cells' since these fit almost exactly the immunologists' design for a surveillance cell in being able to recognise and kill malignant cells without previous sensitisation. The basic observation which drew attention to natural cell-mediated immunity arose out of quite extensive studies comparing the *in vitro* cytotoxicity of peripheral blood lymphocytes from cancer patients and normal donors for cultured cancer cells. Initially these investigations were interpreted to show clear-cut specific cytotoxicity by 'sensitised' lymphocytes from patients, but in later studies by Takasugi *et al.* (*Cancer Res.* **33**, 2898; 1973) and Oldham *et al.* (*J. natn. Cancer Inst.* **55**, 1305; 1975) it became apparent that lymphocytes from normal individuals, who would not be expected to have been exposed to the relevant cancer-associated antigens, were also cytotoxic. Moreover in many

instances the natural cytotoxicity of lymphocytes from normal individuals was even greater than that seen with similar preparations from cancer patients. Natural cell-mediated immunity has since been examined using more closely controlled animal systems and, as in humans, lymphocytes from normal mice and rats have proved to be cytotoxic *in vitro* for tumour cells, especially those of lymphoid origin.

In the mouse and rat, normal killer (NK) cells have been detected in most lymphoid organs, with particularly high activity in the spleen, lymph node and peripheral blood whereas in humans, studies have mostly been restricted to peripheral blood lymphocytes. In mice NK cells develop in the absence of the thymus and appear and disappear in a highly typical manner, reaching peak levels at between 5 and 8 weeks of age. NK cell activity is also under genetic control, allowing the classification of low and high NK cell strains. The position in other species, especially humans, is still unclear, but it has been proposed that NK cell activity may be related to HLA phenotype. The characterisation of NK cells is more controversial and it is this aspect of the problem which leads to most confusion. In the mouse, the NK cell is thought not to be a mature T cell because of its presence in athymic mice, although Herberman and Holden (*Adv. Cancer Res.* **27**, in the press) have suggested that it might be a primitive T cell. The characteristics of NK cells in humans are even less well understood and at present the only point of general agreement is that these cells are not macrophages.

Although it has been implied that natural killer cells may provide the host with a natural barrier against malignant cells, evidence on this point is sparse. The resistance to growth of transplanted tumours, including those of human origin, in athymic nude mice has been correlated with their high levels of natural cell mediated cytotoxicity. This evidence is not sufficiently compelling, however, since

these animals have been reported by Pimm and Baldwin (*Nature* **254**, 77; 1975) to be able to reject tumours through macrophage-mediated reactions. More convincing are studies by Kiessling and his associates (*Int. J. Cancer* **15**, 933; 1975) correlating the growth potential of transplanted tumour cells in different strains of mice with their levels of NK cell activity. Also within one strain Sando *et al.* (*J. natn. Cancer Inst.* **55**, 603; 1975) found that resistance to a transplanted tumour changed with age in a pattern similar to the known age-dependent variation of NK cell activity. These approaches have been further extended in a study now published by Haller *et al.* (this issue of *Nature*, page 609) which provides more direct evidence for a role of NK cells in suppressing tumour growth. Mice were thymectomised, irradiated and reconstituted with anti-T-cell treated bone marrow cells or foetal liver cells. When lymphoid cell donors of a compatible substrain of high NK cell activity were used, the transplanted tumours were rejected, whereas no resistance was observed in mice receiving cells from donors with low NK cell activity. These findings point to the potential of NK cells in tumour resistance, although whether they have a 'decisive role' remains to be established. In this context, it is pertinent that cells with similar characteristics to NK cells can be isolated from tumour biopsies, and that bacterial vaccines such as bacillus Calmette Guérin (BCG) and *C. parvum* which are being widely used in cancer immunotherapy trials markedly influence NK cell activity. One should guard against a too unitarian view, however, since many of the approaches for enhancing nonspecific immunity against cancer by the use of bacterial vaccines are known to require macrophages. Nevertheless the concept of a nonspecific lymphocyte which recognises aberrant cells is attractive for the immunosurveillance concept and augmentation of these cells could have therapeutic potential. □

# Are comets dirty snowballs or dust swarms?

from David W. Hughes

HEATED debates in science are always fascinating and none more so than the long standing one between cometary scientists as to whether comets are made up of a swarm of small, meteoric dust particles or a single kilometric sized icy nucleus. More fuel has been heaped on the fire recently by Lyttleton (*Q. Jl R. Astron. Soc.* **18**, 213; 1977) and Fellgett (*The Observatory* **97**, 23; 1977).

Both authors base their argument on that well worn principle of scientific methodology first propounded by William of Occam in the fourteenth century. Occam's Razor intimates that theories should be based on as few hypotheses as possible. Hypotheses must not be invented merely to explain away difficulties, especially if those hypotheses are not suggested by other features of the phenomena under investigation and cannot be tested in any way.

## Swarm or macronucleus?

How does this apply to comets and especially to the debate between the swarm enthusiasts, of which Lyttleton and Fellgett are the most enthusiastic, and the large army of macronucleus supporters? First, I shall explain the two concepts in more detail. The classical view, held by most people up to the early 1950s, is that a comet is a vast swarm of tiny particles separated by very large distances—around  $10^{25}$  particles of mean size about  $10^{-2}$  cm separated by tens of metres. The average comet diameter is about 100,000 km, average mass around  $10^{18}$  g, spatial density less than  $10^{-12}$  g cm $^{-3}$ . The icy conglomerate model was formalised by F. Whipple in the early 1950s (*Nature* **263**, 15; 1976) and since then it has gained pre-eminence. Here the fount of cometary phenomena is a single kilometric sized body containing about 25% by mass dust particles, the rest being ices of methane, ammonia and carbon dioxide embedded in H $_2$ O snow as hydrates or clathrates. A comet of mass  $10^{18}$  g would have a nucleus about 6 km across with a density around 1.1 g cm $^{-3}$ .

Both these models are hypothetical and as such Occam's Razor seems powerless to distinguish between them. The swarm is so tenuous that it would

have to extend over  $10^7$  km in the line of sight before it ceased to be transparent. A solid nucleus of length 1 km transverse to the line of sight at 1 AU would subtend an angle of less than 0.002 arcs at an Earthbound observer and is thus way below the resolution of all present day telescopes. So both are unobservable.

## Cometary origin

Hypotheses on cometary origin also seem powerless to distinguish between the two models. Swarm comets are supposedly formed by accretion from an interstellar cloud. Particles streaming past the Sun become gravitationally focused downwind, lose energy by inelastic collisions, are retarded to velocities below the escape velocity and then become gravitationally attracted to the Sun, slight perturbations preventing them actually falling into it. Dirty snowball comets are supposedly the remnants of an enormous family of planetismals, some of which coalesced to form the planets Uranus and Neptune. These cometary planetismals were perturbed (by planetary encounters) out of their original orbits to the Oort sphere, a great (but again unobservable!) comet reservoir some 40,000 AU from the Sun, from which they are periodically perturbed by passing stars into orbits with perihelion passages among the planets. Both theories are possible but obviously it requires only a small addition to the interstellar accretion theory to produce icy nuclei anyway. The fact that diffuse interstellar dust and gas clouds are considered to be the parents of stars and planets (and we should at least be convinced that planets exist) does not put this beyond the bounds of possibility. If the planetesimal theory is true, all comets are as old, if not slightly older than the planets (giving them an age just over  $4.6 \times 10^9$  years) and the number of comets in the Solar System must have been decreasing ever since. Fortunately icy nuclei comets can be kept in 'cold storage' in the Oort sphere. Accretion mechanisms have the advantage that the comet family can be enhanced every time the Sun passes through a dust cloud. Here comets can have a wide range of ages.

It is to be hoped that the observations of cometary phenomena can distinguish between the two models. Evidence is needed that points unequivocally at one or the other (or neither).

Unfortunately both models can explain many phenomena with reasonable success. The coma can be formed by desorption from the solid meteoroids in the swarm or by ice sublimation from the nucleus. Desorption is enhanced by the interparticle collisions which take place near perihelion as the individual particles in the swarm move from above to below the median plane of the swarm orbit. Collisions also bring about the emission of light and the release of gases. Sublimation increases as the temperature of the nucleus increases. Meteoroid streams can be formed by the ejection of particles from the nucleus by gas pressure or by the fragmentation of swarm particles.

## Phenomena

The problematic phenomena are as follows. The coma generally contracts as the comet approaches the Sun, roughly in proportion to its heliocentric distance, and then expands again as it recedes. A swarm would do this. However, the observation is much more difficult to explain with an icy nucleus. The sublimation of the different icy species would have to have an unusual temperature dependence to fit the observations.

Some comets engender intrinsic forces which change their periods, this change being non-random and continuing from one orbit to the next for tens of years. The periods can both increase and decrease. Lyttleton explains how perihelion collisions in a swarm can result in a loss of orbital energy and an acceleration of the mean motion. But how can the energy of the swarm increase and the period decrease? With a rotating icy nucleus (and what is not rotating in the Solar System?) any delay in the sublimation process would produce a jet force with a component normal to the solar direction and thus accelerate or decelerate the orbital motion, depending on the sense of rotation.

Comets are seen to split up into separate components which move apart with relative velocities of a few m s $^{-1}$ . Asymmetrical jet action could spin-up the icy nucleus until it breaks up under the action of centrifugal force. It is difficult to envisage how swarms can split up.

Some comets undergo outbursts, sudden increases in brightness which can be as large as a hundred-fold. In

David W. Hughes is a Lecturer in the Department of Physics at the University of Sheffield.

the case of comet Schwassmann-Wachmann I the occurrence of these bears no temporal association with perihelion passage, as would be expected if the comet was a single swarm of particles. An *ad hoc* increase in the number of swarms in an individual comet helps, but goes against the whole tenet of Occam's argument. Meteor studies indicate that Encke has made thousands of orbits around the Sun and this gives Encke a recent inner Solar System lifetime of at least 10,000 years. Long period comets are expected to have lifetimes easily up to ten times this value. The high surface area to mass ratio of the swarm comet would make it a large collision target for the meteoroids in the Solar System dust cloud and collisions with these particles would slowly dissipate the swarm. Also a hierarchy of particle sizes would lead to a conspicuous spreading of the swarm along its orbit over 10,000–100,000 years under the action of the Poynting–Robertson effect. Swarm comets would thus have shorter lives than icy nucleus comets—possibly too short to agree with meteor stream data.

Some Sun-grazing comets actually pass through the solar corona, and the dusty insulating layers surrounding an icy nucleus seem to be required to enable the comet to withstand the intense heat. Swarm particles would vapourise. Even though recondensation is possible, the gas content and thus cometary activity would be much reduced.

### Arguments

These are some of the arguments that crop up in the debate—a debate which is not without its fair share of invective. For example, Whipple (*op. cit.*) dismisses the swarm hypothesis as 'totally unsatisfactory' and O'Dell (*The Study of Comets* part 2, NASA S.P. 393, 591; 1976) describes the swarm and nucleus models as 'the inconsistent and the unavoidable'. Lyttleton in his paper calls the icy nucleus model an 'invalid unacceptable hypothesis' to which has been added 'an elaborate set of ad hoc assumptions to try and escape the difficulties that the initial conjecture itself entails', a model which is 'ruled out at once by the principle due to Occam'. Before introducing the icy nucleus as a hypothesis 'it would be necessary to show with scientific certainty that specific cometary phenomena exist that are incapable of explanation by already available hypotheses'. In other words dust swarm out before icy nucleus in. But why? Surely hypotheses must be judged on their usefulness and not their historicity. Both can be subjected to the scientific rigour of checking and

## A liquid permanent magnet?

from P. V. E. McClintock

ACCORDING to A. J. Leggett (this issue of *Nature*, page 585) there is reason to believe that the A-phase of superfluid  $^3\text{He}$  may display ferromagnetic properties. An isolated sample of the liquid would thus be surrounded by its own spontaneously created magnetic field in much the same way as a conventional steel permanent magnet, although the physical origins of this magnetism would be rather difficult.

The onset of superfluidity (below a temperature of 0.0026 K) in liquid  $^3\text{He}$  is associated with the atoms forming themselves into pairs, each of which can be regarded as being in many ways rather like a giant diatomic molecule, with the two atoms orbiting around each other. A bulk sample of the liquid tries to arrange itself such that the angular momentum associated with each pair lies in the same direction, known as the *l* direction (giving rise to intriguing—and, as yet, unresolved—questions about the possible existence and magnitude of an intrinsic, macroscopic angular momentum for the liquid as a whole). In the A-phase the nuclei of the atoms in a pair are orientated parallel to each other and, because each nucleus carries a feeble magnetic moment, this might seem at first sight to offer the possibility of bulk ferromagnetic properties. It is known, however, that even in a very weak magnetic field the pairs of nuclei tend to align themselves in such a way that just as many lie anti-parallel to the field as are parallel to it. One can be confident, therefore, that the liquid will not develop any intrinsic magnetic field through spontaneous ordering of the nuclei. What Leggett has done is to point to the possible existence of an entirely different mechanism in which it is the electrons of the  $^3\text{He}$  atoms that might be able to produce magnetic effects.

It is well known that in a rotating diatomic molecule the electron shells tend to 'slip' a bit: the atoms forming the molecules do not orbit each other like rigid spheres. Thus, a little of the rotational angular momentum of a molecule gets transferred to the electrons around each of its two constituent atoms, producing electrical currents which in turn give rise to magnetic fields. For a conventional diatomic gas, however, the net magnetic field resulting from this phenomenon averages to zero because all the molecules are orientated at random relative to each other. (The effect may still be observed, though, from the broadening of nuclear magnetic resonance lines resulting from the randomly modified local magnetic field in which each nucleus finds itself.)

For  $^3\text{He-A}$ , on the other hand, the 'molecules' form a highly ordered system, so that the magnetic contributions of different pairs will reinforce each other, producing a macroscopic magnetic field whose direction will depend on that of the *l* vector. Leggett estimates the magnitude of this field, and he reaches the conclusion that it should be detectable in a suitably designed experiment.

If superfluid  $^3\text{He-A}$  is really ferromagnetic—and, on the basis of the simple 'giant diatomic molecule' model of the pairing, this conclusion seems to be almost inescapable—there will, as Leggett points out, be a number of interesting implications. Not least is the fact that the superfluid would apparently have been found endowed with yet another form of uniqueness: as being the only ferromagnetic liquid known in nature.

*P. V. E. McClintock is a member of the Department of Physics at the University of Lancaster.*

improvement. To quote Leggett: 'it is not permissible to go on copying the same assumptions from one publication to the next, while simply ignoring either the contrary evidence or the lack of positive evidence'. So the adherents of the swarm hypothesis must investigate explicitly how a swarm can accelerate as well as decelerate in its orbit, how it can split up, produce outbursts, and how it can exist as a specific entity for  $10^4$  to  $10^5$  years. Those who favour the icy nucleus must again carefully investigate processes which can produce the

observed variation of coma size with heliocentric distance, the asymmetry of coma brightness, and the sometimes quickly varying spatial and temporal light condensations in it. But how can we satisfy Lyttleton?

He predicts that there is little possibility of this argument being resolved 'short of some startling optical development useable from Earth, or that the Earth should run directly into a long-period comet or a successful cometary mission has been carried out with equipment capable of finding the nucleus if it is there'. The second of these points

could, however, have been satisfied. Comets are not rare and Earth must have run into many in its lifetime. Brown and Hughes (*Nature* **268**, 521; 1977) found that a small  $5 \times 10^{10}$ -g comet hits Earth on average about every 2,000–4,000 years. Now swarm nuclei have cross-sectional areas about 60 times that of the Earth. An Earth-swarm impact would be equivalent to an intense and very short lived ( $\sim 1$  h) meteor shower. Unfortunately this would be indistinguishable from the phenomena produced by the passage of the Earth through an active new meteor stream. On the other hand, an impact between Earth and an icy nucleus comet would produce a large explosion low in the atmosphere or at ground level; Brown and Hughes proposed the Tunguska event as a strong candidate for just this type of impact. Unfortunately the surface evidence of such a cometary impact would be wiped out by erosion and the regrowth of vegetation after a relatively short time ( $\sim 100$  years). So we are lucky that Tunguska occurred only 70 years ago and is still evident. Older impacts have long since been erased. Needless to say, to propose that Tunguska was probably caused by a cometary impact is a far cry from regarding the Tunguska event as definite proof that comets have small dirty snowball nuclei.

I think the evidence is strongly balanced in favour of the icy nucleus model but it must always be remembered that it is only a model, not established fact. We still are far from knowing what a comet is for certain.

## Gel motility

from Dennis Bray

LIKE the electron, the cell shows a different face according to how it is treated; at least, that is the conclusion to be drawn from recent papers on cell movement. Even the intuitive picture of the inside of the cell seems to depend on the techniques used. To the biochemist for example, who isolates actin and myosin from various tissues, the cytoplasm appears to be full of miniature muscles. Membrane-anchored actin filaments slide against short myosin segments and in this way generate cell extension, membrane flow and intracellular movements. This 'biochemical' view has the unique advantage that it gives immediately the molecular details of force generation, but the overall picture is very blurred. How the small contractile elements are to be distributed and coordinated within

the cell is problematic and left largely to the imagination. By contrast, the 'cytoskeletal' view—which has been engendered mainly by the use of fluorescent antisera—shows the position of the fibrillar proteins directly. Here the cell is a complex basketwork of actin cables, microtubules and  $100 \text{ \AA}$  filaments, sometimes linked together in a geometrically precise fashion. The relationship of the different proteins to each other can be seen in gross terms, but so far it has not been possible to go down to molecular dimensions. Moreover, this picture has a distinctly inflexible quality and movement with such accessories calls to mind the grudging articulation of a child's construction set.

Most recently a number of investigators have, at least by implication, returned to what might be called the cytoplasmic or 'amoebic' view. They see the cytoplasm as a substance that can flow or set on demand and thus produce within the confines of the membrane the means of locomotion. The experimental basis of such work is the cell-free extract that can either move or change its consistency in a meaningful way. This was first shown to be possible in an experiment of Allen and coworkers (*Nature* **187**, 896; 1960), and a major part of the contemporary work is a direct descendant of this. As summarised by D. L. Taylor (*Cell Motility, Cold Spring Harbor* 797, 1976), the cytoplasm of free-living giant amoebae may be isolated into various test solutions where it responds according to their composition. Without free calcium the cytoplasm is immotile and lacks birefringence while the addition of as little as  $7 \times 10^{-7} \mu\text{M}$  calcium will cause contraction. Cells ruptured in threshold concentrations of calcium will extrude cytoplasmic 'flares' very like pseudopodia without their membranes. These transitions have been related to changes occurring within the intact amoeba and, in turn, there are indications that they depend on the state of aggregation of the cytoplasmic actin. The latter feature has been shown very clearly in recent work on the slime mould *Physarum* in which, as in amoeba, the rapidly streaming cytoplasm has two distinct phases. Isenberg and Wohlfarth-Bottermann (*Cell Tiss. Res.* **173**, 495; 1976), examined the droplets obtained by puncturing the organism which are at first sol-like and then change in consistency and mechanical strength to produce a gel. The drops were allowed to spread on the surface of small aliquots of buffer and then caught on an electron-microscope grid. Under the right conditions, within 5 minutes or so, a dramatic increase

occurred in the numbers of actin filaments concomitant with the maturation of the droplet: strong evidence that actin polymerisation is involved in the sol to gel transformation.

Another lineage of experiments, arising from a different initial observation but converging to a closely analogous position, concerns motile extracts of giant amoeba, acanthamoeba, slime moulds, sea urchin eggs, macrophages, leukaemic cells and HeLa cells. These systems were recently reviewed by Hitchcock (*J. Cell Biol.* **74**, 1; 1977), to whom the interested reader is referred. These extracts resemble the isolated amoeba cytoplasm in many of their properties but since they involve a number of purification steps they are—in spirit if not in simplicity—considered as biochemical preparations. They share an initial extraction into ice-cold buffers lacking calcium and containing ATP, and most of them use either sucrose or glycerol. They all show a temperature-induced gelation and they all have as their major component actin.

Beyond this the differences are many and somewhat confusing. Compare, for example, a recent paper on *Dictyostelium* (*J. Cell Biol.* **74**, 901; 1977), with one on cultured HeLa cells (*J. Cell Biol.* **75**, 95; 1977). One uses sucrose and a detergent in the extracting solution, the other a simple buffer; one extract will contract after gelation, the other will not; only a handful of the 20 or so proteins present in the extracts are obviously comparable, and so on. The burden to the casual reader is not made lighter by the zeal with which the workers in this field publish the minutiae of their results and their papers are characterised by the number and complexity of tables of ionic effects and figures showing protein composition. If there are general conclusions to be drawn from the comparison of various systems, the authors do not make them easy to find.

This is not a trivial point because it is possible to become data-drunk and confuse the formal similarity between the various observations for a common mechanistic basis. One can finish with the belief that the patently major cytoplasmic streaming and sol-gel transformation of a free-living giant amoeba is true of a vertebrate tissue cell: it may be so; but it has not yet been shown. Most importantly, the fact that these various sources can all yield protein gels is not evidence of a common physiology. Most proteins will form a gel if they are sufficiently concentrated—including muscle F-actin left in a refrigerator for 2 weeks—and their consistency and mechanical properties will inevitably depend on temperature

and ionic composition. No doubt there are gels and gels; but techniques are not available to make subtle distinctions. The usual test of how an extract falls out of an inverted tube is no more scientific than the criterion advanced by Fats Waller: that it must be jelly 'cause jam don't shake like that!

To be fair, the investigators are aware of these problems and make every attempt to relate the phenomena they are studying to cellular physiology. Already there are encouraging signs, such as that the contractile properties of a macrophage extract depend on the phagocytic activity of the cells (Stossel & Hartwig, *J. Cell Biol.* **68**, 602; 1976), and that cytochalasin B has a pronounced effect on the properties of some gel systems (Weihsing *J. Cell Biol.* **71**, 303; 1976; Hartwig & Stossel *J. Cell Biol.* **71**, 295; 1976). One can hope that the motile gels will be further dissected and even that they can reconcile the presently diverse views of cellular locomotion. We are so spoiled by the example of striated muscle—where the whole range of movement, from macroscopic changes in length down to molecular or even submolecular changes, can be linked in an unbroken series of logical steps—that nothing less will do. □

## Relevance of parasitology

from F. E. G. Cox

The British Society for Parasitology autumn meeting on The Relevance of Parasitology to Human Welfare Today was held in London on 28 October, 1977.

THERE is no doubt that parasitology has taken off, but it is germane to ask if some of it may actually have gone into orbit. It is, therefore, essential for parasitologists to get their feet back onto the ground and that is what this meeting was about. In the morning B. O. L. Duke (World Health Organisation (WHO), Geneva) spoke about medical aspects of parasitology, R. B. Griffiths (Food and Agriculture Organisation, Rome) about veterinary aspects and P. T. Haskell (Centre for Overseas Pest Research, London) about agricultural aspects. In the afternoon two invited speakers commented on each of these aspects and introduced specific and general discussion.

The morning's speakers set the stage,

F. E. G. Cox is Professor of Zoology at King's College, London.

summarising the main areas of interest to and reiterating the parasitological problems of the developing world. The WHO Special Programme (*News and Views* **262**, 85; 1976) was outlined, but there can be few parasitologists who do not know what the questions are and no real attempt was made to provide any answers. The Special Programme is arguably one of the most important events in the history of parasitology and it would be a pity if it deflected attention from parasites which are not of medical importance. Griffiths left no doubt that diseases such as fascioliasis, trypanosomiasis and theileriasis maintain a stranglehold on meat production in the tropics, and singled out ticks as the major vectors of the diseases of domesticated animals. Considerable progress has been made in the control of these diseases—new and effective anti-trematode and cestode drugs such as Praziquantel are now available and successful immunisation of cattle against east coast fever has been achieved. Less dramatically it has been shown that larval stages of tapeworms which are not infective to man can be differentiated from those that are, making it possible to save vast numbers of carcasses. It may be that the amount of meat saved as a result of parasitological research is not much by western standards, but it is a major contribution towards raising the standard of living in the developing world and supporting the increasing population which will result from WHO activities.

Agricultural improvements are also necessary for the future of the developing world and there is evidence that the problems are not insoluble although insecticides will remain the major tool for many years to come. There is, however, much more that needs to be known about tropical ecosystems before it becomes possible to modify local or devise new agricultural methods, for it is now clear that the transplantation of western ideas and techniques creates new problems as well as solving some of the existing ones. In particular, the importance of plant nematodes is only just being understood (J. Bridge, Imperial College, London), and the differences between their activities in tropical and temperate lands may be immense. Land use in the tropics, especially Africa, is a perennial topic for discussion and W. E. Ormerod (London School of Hygiene and Tropical Medicine) drew attention to the limitations that soil and rain place on land use (see also Ormerod *Science* **191**, 815; 1976). The use of indigenous animals as sources of food was discussed, but possible parasitological problems were not considered.

One of the major sources of disquiet

discussed was the lack of any real future for drugs against parasitic diseases. J. F. Ryley (ICI Ltd, Alderly Park) pointed out that the development of any drug was now prohibitively expensive, mainly because of the regulations embracing such developments. The WHO also laid down conditions which effectively prevented many pharmaceutical firms from co-operating in joint ventures. Participants at the meeting were pleased to learn that these conditions are to be changed.

Another source of disquiet was the lack of career prospects for young parasitologists. Graduate unemployment is a world-wide problem and developing countries naturally wish to employ nationals in WHO and other schemes. The disenchantment of young people who have a real interest in parasitology and its direct application but who find that they cannot work where they feel they are needed is real. G. S. Nelson (London School of Hygiene and Tropical Medicine) drew attention to the achievements of parasitologists in the past and the important discoveries made by Britons in this field. It may well be that, in the past, devoted parasitologists working in less than optimal conditions took the assistance of local staff for granted. Perhaps the great discoveries yet to come will be made by local parasitologists and young Americans and Europeans will be better employed as their highly skilled technicians. It takes courage and real devotion to do the work and receive none of the glory, but the great achievements listed by Nelson were those of men who thought more about sick Africans than the number of papers published. □

## Two-photon ionisation interference effects

from Peter Knight

AN atom in a moderately intense laser field can ionise by absorbing more than one photon, and multiphoton ionisation is a very active subject at the moment. For example, it was hoped that the multiphoton ionisation of an alkali could provide, by courtesy of the spin-orbit interaction, a useful source of spin-polarised electrons. Preliminary experiments were performed at several laser wavelengths on the two-photon non-resonant ionisation of atomic caesium ( $\text{Cs} + 2h\nu \rightarrow \text{Cs}^+ + e$ ) by Van der Wiel and

Peter Knight is Jubilee Research Fellow in the Department of Physics at Royal Holloway College, London.

Granneman (*J. Phys.* **B8**, 1617; 1975). Much to everyone's surprise large discrepancies, of up to four orders of magnitude, were found between experiment and until then currently accepted theory. A predicted deep minimum of 2.6 eV photon energy in the two-photon ionisation curve arising from cancellation of 6p and 7p intermediate state contributions is entirely absent in the experimental data. Three years later, after much theoretical and experimental work, the problem remains, with no sign of a successful explanation. Similar paradoxical situations exist in the multiphoton ionisation of other atoms.

The experimental two-photon ionisation rates,  $P_2$ , are measured away from intermediate atomic resonances and at low enough laser intensities  $I$  to avoid saturation. Then the two-photon ionisation generalised crosssection  $\sigma_2$  at laser frequency  $\omega$  can be defined through  $P_2 = \sigma_2 \langle I^2 \rangle$  and  $\sigma_2$  is described by the second order perturbation result

$$\sigma_2 \propto \left[ \sum_n \frac{\langle f|r|n \rangle \langle n|r|g \rangle}{\omega_n - \omega} \right]^2$$

The atom is presumed to start in some initial state  $|g\rangle$ , end up in a continuum state  $|f\rangle$  and we need to sum all intermediate states  $|n\rangle$  of energy  $\hbar\omega_n$ . Often, as here in Cs at 2.6 eV, there is destructive interference amongst the terms in the sum: all signs are equal except energy denominators and  $\sigma_2$  should exhibit a deep minimum sometimes called a Fano or Cooper minimum. Problems facing the theorist involve finding accurate (although necessarily approximate) values for atomic wavefunctions using quantum defect, model potential or other methods and then to perform the summations. The existence and properties of the minimum have been reinvestigated by Teague *et al.* (*Phys. Rev.* **A14**, 1057; 1976) again assuming the validity of second order perturbation theory. They find the position of the minimum is insensitive to the choice of wavefunctions. There is some disagreement between theoretical results obtained by different methods, but they all differ very much more from experiment than from each other.

The original experiments of Van der Wiel *et al.* were performed using the nine argon-ion laser wavelengths available, and were calibrated by normalisation to a known one-photon cross section measured using frequency doubled laser light. The quadratic intensity dependence of  $P_2$  (and therefore the absence of saturation) was checked using neutral density filters. Since it is only a two-photon process, photon statistics of the laser light are relatively unimportant (they can contribute a factor of two at most). One problem is the contribution dimers make to the ion signal by processes such as

Relatively few dimers can provide a larger count rate than the numerically superior free atoms because they are resonantly enhanced and have a large density of resonant states. This molecular effect potentially can fill in the experimental minimum, but Van der Wiel and colleagues at FOM have studied these processes in detail (Granneman *et al.* *J. Phys.* **B9**, 865; 1976; Klewer *et al.* *J. Phys.* **B10**, 2809; 1977) and believe they have the dimers under control and that the discrepancy is not due to molecular background. Another possibility was that the minimum lies below the lowest energy available from an argon ion laser. This possibility seems now to have been eliminated (Klewer *et al.* *J. Phys.* **B10**, L243; 1977) by using an argon-ion pumped Rhodamine 6G dye laser to study two-photon ionisation at photon energies from 2.2 eV to near the two-photon threshold at 1.95 eV. Provided the temperature is raised sufficiently to remove dimers no detectable atomic two-photon ionisation remained in the wavelength at the (lower) intensities available from their dye laser. The data from all the wavelengths is compared with the best current theory in Fig. 1. In the same paper the ratio of the ion count rates obtained from two-photon ionisation of Cs atoms using linearly and circularly polarised light at the nine argon-ion wavelengths were measured. Again there is disagreement with theory, with the experimental ratio ( $\sigma_2(\text{circ})/\sigma_2(\text{lin})$ ) lying significantly below the 'best' values of Teague *et al.* except close to a  $7P_{1/2}$  intermediate resonance.

So we are left with a considerable problem. The approximate position of the Cooper minimum in the two-photon ionisation is determined by only a few matrix elements corresponding to transitions to nearby levels. Other levels shift the minimum by only a small amount.

**Fig. 1** Two-photon ionisation probability of Cs as a function of photon energy.  $\circ$ , Granneman and Van der Wiel (*J. Phys.* **B8**, 1617; 1975);  $\bullet$ , Klewer *et al.* (*J. Phys.* **B10**, L243; 1977).  $\dagger$ , upper limit found in the same ref.; full curve, Teague *et al.* (*Phys. Rev.* **A14**, 1057; 1976) theory. (Taken from Klewer *et al.*)

It would require a change in sign of either the matrix elements  $\langle 6p|r|6s \rangle$  or  $\langle 7p|r|6s \rangle$  for the deep minimum not to occur. Obviously more theoretical work on the calculation of  $\sigma_2$  is needed. Even the validity of second-order perturbation theory to describe the two-photon ionisation has been investigated, by Crance and Feneuille (*Phys. Rev. A*, in the press) who studied the time development of the pulsed photoionisation using a model introduced by Armstrong, Beers and Feneuille (*Phys. Rev.* **A12**, 1903; 1975). They have found some effects due to the finite pulse length, but their model is a little idealised. More experimental work is needed and this is being undertaken in various laboratories. Looking for a minimum is hard when background molecules are only too eager to fill the sought-for trough and future experiments will need to pay special attention to this problem.  $\square$

## A hundred years ago

DR. VOHL, of Cologne, has adopted an ingenious method of determining the impurities in the Rhine, which consists in analysing the boiler incrustations of the river steamers, as well as the concentrated residues remaining in the boilers after passing over a certain distance. By this means he has detected the presence of a large amount of arsenious acid in the river water—resulting chiefly from the aniline and dyeing establishments—as well as other poisonous substances. An unusually

high percentage of phosphoric acid showed that the sea was daily absorbing vast quantities of the most valuable fertilising material from the soil of Germany.

ANOTHER sitting of the enlarged Council of the Observatory of Paris was held on December 9. The councillors passed a resolution for an increase of the salary of the astronomers and auxiliary astronomers, the maximum pay of the former to be 10,000 francs instead of 8,000, and of the second 7,000 instead of 6,000. They propose to the Government to place the appointment of the director of the establishment partly in the hands of the Academy of Sciences and partly in the hands of the Council, the Minister to have only the privilege to choose between both presentations. From *Nature* 17, 13 December, 131; 1877.

THE lunar geological formations known collectively as the Fra Mauro Formation have long been thought, by most students of the Moon, to be deposits of ejecta from the basin of Mare Imbrium. When, in 1971, Apollo 14 astronauts surveyed an area not far from the crater Fra Mauro itself, it was hoped that new light would be thrown on this old conjecture.

The *US Geological Professional Paper 880*, US Geological Survey, 1977 examines merely a part of the apposite evidence: that relating, principally, to the astronauts' *in situ* findings and their hand-held camera records. Accounts of the terrain characteristics and of numerous rock blocks feature prominently in the description. The rock blocks range up to several metres in size. They are all breccias thought to have been produced by the welding of impact-generated fragments. The photogeological analyses of these rocks cover discussions of their structures and descriptions of their clasts. One block of rock has a probable clast, 1.7 m in length, in which other clasts are found and which themselves contain yet other probable, small clasts: this indicates successive and discrete stages in the evolution of this particular block.

The photointerpretation is supplemented by the astronauts' own field descriptions of the samples; and the publication includes coloured geological maps, charts, and panoramic photomosaics to assist the reader with the identification of a sample's relative position and environs.

Good descriptions are presented of three kinds of rock fillet—an accumulation of fine-grained material (see photo) making contact with a co-

## Surveying the Moon

from G. Fielder

herent block or rock—and of other features which point to physical processes on the lunar surface. Among these features, the lunar grid (lineament) system is put in perspective when the authors argue for the correlation of small-scale (centimetre to metre lengths) lineament trends with trends mapped on a large scale and dismiss the proposition that lighting

can have an all-important bearing on the apparent directions of most lineaments.

Although the matrix materials of the rocks studied in detail on this fine collection of photographs are frequently referred to, in the text, as of probable Imbrium origin, the Fra Mauro Formation is said (without qualification), in the Summary of Conclusions, to consist of ejecta from the Imbrium basin! □

G. Fielder is Head of the Lunar and Planetary Unit at the University of Lancaster.

One of three kinds of lunar fillet: lunar regolith fines have been scattered on to this gently sloping, structured rock face and have settled in shallow depressions to produce a 'low angle fillet.' (NASA photo AS-14-68-9450)

## Benioff splitting

from Peter J. Smith

BENIOFF ZONES are intimately associated with earthquakes. Indeed, earthquakes provide the best means of delineating such zones, indicating with startling clarity how moving oceanic lithosphere bends downwards beneath appropriate continental edges and descends at an angle of about 45° until it is ultimately assimilated into the mantle. But whereas it is customary to see a scattered pattern of earthquakes defining the outlines of a descending plate, more recent observation has indicated the presence in some

cases of a fine structure of seismicity which may throw light on at least one of the processes by which Benioff zone earthquakes are produced.

A nice example is provided by Engdahl and Scholz (*Geophys. Res. Lett.* **4**, 473; 1977), who have analysed the distribution of foci from all earthquakes with magnitude greater than 3 occurring from July 1974 through February 1977 in the Adak region of the central Aleutians. The resulting plot shows that most of the shallow seismicity in the area occurs within the depth range 15–27 km and has a lateral spread of about 50 km in the direction of the horizontal component of plate motion (that is, viewed in side projection, looking end-on at the arc). Immediately below, the zone of seismicity then contracts to a lateral width of no more than 10–15 km. At a depth

of about 100 km, however, the seismicity splits into two distinct zones each of which has a lateral dimension of 10–15 km and is separated from the other by a practically earthquake-free region about 25 km wide. At a depth of about 175 km the two arms then come together again, forming a single zone of seismicity down to the deepest earthquakes at about 270 km.

This is not the first known example of Benioff splitting. Sykes (*J. geophys. Res.* **71**, 2981; 1966) observed a separation of about 30 km in the pattern of intermediate earthquakes beneath the Kurile arc more than a decade ago; and more recently Veith (thesis, Southern Methodist University, Texas, 1974) and Stauder and Mualchin (*J. geophys. Res.* **81**, 297; 1976) have investigated the Kurile case in greater detail. Umino and Hasegawa (*Zisin* **28**,

Peter J. Smith is a Reader in the Department of Earth Sciences at the Open University.

125; 1975) have also demonstrated the existence of splitting beneath Japan. In each case the earthquakes in the upper arm of the split indicate down-dip compression whereas those in the lower arm show down-dip tension.

But is such splitting typical or atypical of Benioff zones? And either way, what causes splitting and the associated difference in focal mechanism? The answer to the second question may well suggest an answer to the first. One possible explanation is that the two arms of seismicity represent two closely associated, but distinct, descending slabs. But although this possibility is not inconsistent with the Adak splitting, it cannot, according to Engdahl and Scholz, account for the Japanese and Kurile examples; nor can it explain the difference in focal mechanisms in any of the three cases. Then it is possible, as suggested by Veith, that splitting is related to the olivine-spinel phase transition, although Engdahl and Scholz make no comment at all on that.

What they do, however, is to propose, following Isacks and Barazangi (in *Island Arcs, Deep Sea Trenches, and Back-Arc Basins*, edit. by Talwani M. & Pitman W. C., American Geophysical Union, 1977), that splitting is due to deformation of the lithosphere during subduction, and to follow up the proposal by constructing a model which seems to account for the observation. The basis of the model is the fact that subducting lithosphere bends at shallow depths but straightens out again as it moves at an angle towards the mantle. Whatever the cause of these changes, the 'unbending' must produce stresses in the descending slab; and Engdahl and Scholz are able to show with little difficulty that, at the observed depths of splitting, an 80-km thick lithosphere has a 22 km thick elastic core with down-dip compression on its upper surface and down-dip tension on its lower surface.

Thus the double zone of seismicity can be explained simply as the result of the release of unbending stresses above and below an elastic core within the lithospheric plate. Moreover, as the plate descends into hotter and hotter regions the elastic core will get thinner and ultimately disappear altogether, which explains why splitting occurs only over a limited depth range below the initial bending of the lithosphere and does not persist to all depths. Since unbending must occur in most, if not all, descending plates, it follows that splitting must be typical of Benioff zones. Failure to observe it in any given case presumably therefore reflects only insufficiently detailed observation and analysis of earthquake foci. □

## Jeffreys Lecturer links Sun and weather

from John Gribbin

IN this year's Harold Jeffreys Lecture of the Royal Astronomical Society, presented on November 11, J. W. King of the Appleton Laboratory reported the latest work of his team on 'The Influence of Solar Phenomena on Weather and Climate.' Over the past few years, King and his colleagues have received a rough ride from some quarters for their failure to explain the physical basis of the links they have found between Sun and weather; commenting here that the situation is no different from that in climatology, where we know the Earth's climate does change without being able to say exactly why it changes, King went on to present convincing evidence of the reality of the link on timescales down to days, and threw out the challenge to both solar physicists and meteorologists to join the Appleton team in investigating these phenomena further.

To most of the audience, and most readers of *Nature*, the debate about solar influences on weather over the sunspot cycle and longer periods must already be familiar. But the new work from the Appleton Laboratory concentrates instead on much shorter term influences, associated with the roughly 27.5 d rotation period of the Sun. The 'signature' of this rotation shows up clearly in such meteorological parameters as the height of the 500 mbar pressure level in the atmosphere, as well as influencing ionospheric properties. In some danger of numbing his audience with overkill at times, King hammered home the reality of these links with a wealth of data, the most intriguing of which showed clear geographical variations of the magnitude and even sign of the atmospheric changes produced by the Sun. Small wonder, then, that global averages over long periods show much less indication of any solar influence on weather!

The solar influences are particularly strong in a region above the Atlantic just west of the British Isles, which makes this link between Sun and weather especially important for residents of those islands. And if these small variations over the solar rotation cycle can affect weather parameters, then it comes as no surprise to find specific larger events on the Sun—flares and so on—producing specific larger disturbances of the Earth's atmospheric systems.

Such a link has, in fact, been known for some 30 years, since the pioneering work of Duell and Duell (*Smithsonian Misc. Coll.* **110**, 8; 1948) but has only relatively recently become firmly

established (see, for example, Olson *Nature* **257**, 113; 1975). The Appleton team have now found that not only does a solar flare produce a disturbance of the atmosphere, commencing some four days after the flare, as shown by the work of Olson and others, but that the atmospheric disturbance is repeated at 32 and 60 days as well, one and two solar rotations later. In at least one case, an effect on the atmosphere is also found at -24 d, that is one solar rotation before the flare became apparent. So a specific region of the Sun which is involved in some disturbance can affect specific regions of the Earth's atmosphere over a period of 2-3 months—and, equally, the effects of solar activity which are disturbing the atmosphere today must be the integrated effects of several such past disturbances, which suggests that we should not find any simple relation between what the Sun is doing today and what the atmosphere does tomorrow.

King also described investigations of the longer run of data, going back for 100 years, available from UK Met. Office statistics, and these show a clear influence of the solar activity on occurrence of westerly weather patterns over the UK, that is, the weather coming from the region of the Atlantic where the solar influence is strong, and moving towards the British Isles. But this evidence was merely the icing on the cake of his presentation.

The challenge to meteorologists is clear, since these effects are certainly large enough that by ignoring them all the present general circulation computer models (GCMs) must be in error. Could this be why such models are notoriously unreliable if run for more than a few days ahead? And equally the challenge is there for the solar physicists to explain what is going on—with the incentive that the work becomes of direct importance and value now that the link with the weather is emerging.

So King closed by saying that the pathfinding stage of this Appleton Laboratory work is now at an end, with the establishment of the reality of the Sun-weather links. In this essentially interdisciplinary study, the time has come for collaboration between the Appleton group at the centre and the meteorologists and solar physicists on either side; 'I hope,' he said, 'that this lecture will mark a starting point in progress towards achieving practical benefits.' □

John Gribbin works at the Science Policy Research Unit at the University of Sussex.

## My Uncle Eustace—Maker of Rings (1885–1916)

A HAPPY solitary child, after  
his mother died so self contained  
and yet attached by magnet  
chain to Margaret the country girl  
who mothered him at Vicarage;  
his father never understood  
or tried to peel, excise  
the layers of his mind, beneath  
the courtesy, the grave concern  
so strange in one so young, one sensed  
always a sunlit glow, a pool  
of quiet stillness that no naval mine,  
no six-inch shell could shatter.

He passed, as far as clerical  
finances would permit, to prep., then  
boarding school, no niche  
seemed ready carved, a solitary boy  
puzzling to House and Form  
master and sixth form prefects, yet  
always just scraping through  
two from the bottom everywhere,  
cold shouldered, taunted, ragged  
he would endure quite unconcernedly, until  
one famous bully, older by two years  
provoked him ceaselessly and on one afternoon  
when batting on the Common, suddenly  
young Eustace threw down his bat and strolled  
slowly down pitch and felled  
braggart to turf with one fierce swing.  
Always, when this deed had sunk  
swiftly to groundswell, not merely left  
in peace but elevated to that slot reserved  
for the eccentric, rare, unique, original.

One confidant he found, old Bony Head  
the science master who could sense  
a mind attuned intuitively to select,  
assess causal relationships, communicating flows  
built up from pulsing waves in orbit,  
sure, symmetrical, cast in one mould, one unitary mass.

Astounded and affronted was his family,  
that hierarchy of patrons, chiefs,  
that network with edges pinned in Burma,  
Delhi, London when he gained  
a science scholarship to Trinity,  
a field, a slippery slope fit  
for no gentleman to tread and yet,  
with mother's tiny nest egg to augment,  
how could he be gainsayed?

Sheep-like he merged within the Cambridge  
landscape; who knew or cared  
exactly where his lodgings lay  
or whether he built up  
stable relationships? He never said  
how marvellous those days, how glorious the golden youths  
with whom he melted smoothly down in Hall  
or rowed in college eight.  
Always and only shone an inner light.

His tutor was non-plussed because  
over the wide field of chemistry, he barely  
could pass muster, might just expect  
to scrape a Third and yet in one small  
unexploited corner of the craft he delved  
and bored and quarried ceaselessly;  
the hetero-cyclic, alicyclic rings,  
those compounds linked from carbon, nitrogen,  
oxygen, phosphorus and halides, elements  
rare, of dubious and unestablished  
property and mass and controversial valency  
and metals of odd groups, forced them to bind,  
adhere in hoops and circles, cubes  
and boats and knotted cord-like  
thongs; these problems he devoured,  
consumed with every meal, by them  
he was possessed, their literature he absorbed  
in tiniest detail, their personalities,  
their history; as then there was no other specialist  
at hand, this bred a bright hot fury of debate  
whether he merited a First, a Third, a Pass.  
Faith won the day, though outwardly indifferent,  
or so he claimed, so long as he could scoop  
a bursary to study for two years at Heidelberg,  
the fountainhead and spring of all clear waters  
here in this smooth fluency in which  
his flimsy ship was launched, must sail  
and pitch and toss on ocean till it sank  
shipwrecked on rocks, or ran relentlessly  
to calm deep water harbour.

But Eustace never felt at home with Germans,  
yet from them learnt all that he could,  
kept secret much, ploughed down to dusk  
and thirty days a month, except  
for Sundays when he'd read and walk  
to early service in the English church;  
how, in those days, these days, those ever  
other days can one combine science  
with Christ? Well, Eustace tried and yet  
he'd never talk, explain, attempt to justify,  
but said 'it's part of me and always will be,  
so please don't push me further'. How much  
privat-docents, professors knew  
or cared or understood about his bench-work  
problematical. Much that he wrestled with  
he never spoke about, he sealed his notes  
tight locked within a safe. After two years  
his thesis was submitted, was so unique,  
outside all normal channels, unbelievable  
until one sub-professor delegated for two months  
repeated parts in the minutest detail  
and found each component and experiment  
immaculate, repeatable with all analyses  
confirmed in unimpeachable statistical  
integrity; in essence so non-plussed  
the academical establishment, so much at doubt,  
so acrimonious the conflict that at last  
his D.Phil. was awarded and they asked  
that he submit his name for hierarchical preferment.  
Eustace said 'NO' and coming home in nineteen  
ten found no response from British  
chemical grandees in any university.  
Instead, sensing in bone that school

or industry demanded volumes of life-blood he dared not lose and live, would dislocate all plans for studies targetted, he ferreted instead a newly mortared niche in red brick college of technology in Yorkshire. Here, simply was demanded three lectures weekly and all the space of evenings, week-ends and Long Vacations free to theorise, experiment and scribble round the clock.

All work, you say, no private life and so it might have been had he been able to forget those German years; within his blood-stream multiplied the germs of fear, of certainty of wars to come. Exactly numbered days and calibrated therms of energy he gave to Territorial Brigade of Heavy Artillery, became an adept at range-finding, the most professional of officers from whom Colonels of regulars bent down to claim advice. Upon parade he stood one rank beneath my father, who, since a boy-hood thirled to the Lovat Scouts was always army mad. I never knew another so assiduous at work, at drill. He breathed in Elgin ice clear air where grandfather was bank cashier but dad determined from the very day he learnt to read to mount two ladder rungs beyond his family, became Chartered Accountant, then set up in solitary practice here in Yorkshire, where his twin Fiona kept house for him and taught German and English in Ladies' Private School.

Enmeshed by such a pair, how could poor Eustace disentangle from the cords of fishing net? My Aunt Fiona was not outwardly clever at all, a quiet fair haired filly, she seldom spoke so that the Head judged her to be submissive, compliant and then finances being strained, conveniently forgot Fiona's name on the Promotion List and when her resignation came by the first post next morning, a Parents' Protest Committee quickly crystallised and threatened to remove their girls to local Grammar. So, my uncle equally became submissive, really in fact enjoyed his thralldom, as she controlled all family affairs and left his week-ends free for pure research and gunnery.

A scientist is judged by all he publishes, the volume and the quality, the range of the discoveries and theories that appear in journals of accredited repute, the details of the fields that he has ploughed, the implements and measures at the base of tower and palace and with what ease his syntheses were found repeatable and could be used as spring board for fresh thinking. As my uncle Eustace published *nothing*, his reputation faded by neglect and he was soon forgotten by the élite of academic chemistry.

One Sunday, after tea, both families still sitting round the cloth, we children, cousins, were dismissed to garden. Rain, lightning shattered down and we returned to the worse thunder of a family dispute. 'To Hell', my father shouted, 'with academic honour. "May science never be any damn use to anyone" is fine for younger sons of viscounts but not for you, young Eustace, you don't possess a bean and when war comes, what will you leave your wife and kids to live on, if we're killed, as very well we may be; why should they starve because you are too proud to patent, publish your really rare discoveries? Now, fetch them out this minute, there's a good lad and we'll discuss their possibilities.' Fiona sided, not with my father but with her husband, swore she'd work and could support them all. But Uncle Eustace, in sudden silence, strode to his study and thence bore back a pile of manuscripts. While we all watched, in silent awe, the two men there and then selected ten of his theses which my father slipped away, for processing by patent agent friend.

When nineteen fourteen broke, the Battery with other amateurs was very soon immersed in battle. For two whole years my uncle strove with howitzers and mortars. His easy skill soon earned promotion and he found himself a temporary major at Army Corps Headquarters but, odd man out as usual, this election served only to convey boredom, so he transferred to Flying Corps and brought to bear his ingenuity in coaxing speed, manoeuvrability, quick reflex action from his Sopwith Scouts, high above battlefields in dog fight and reconnaissance.

Your past will find you out, advance upon you and on one August afternoon, recalled to C.O.'s hut he was commanded to collect all gear as he was ordered back to Ministry in Whitehall where the back-room boys had delved among his patents and discovered there the basis for a new, intensely powerful explosive which might win the very war. My uncle, angry, overruled, strolled slowly across airfield to his plane, to bid good-bye, as to a favourite terrier dog and at that hour the German fliers dived from cloud to rake the 'drome with fierce machine gun fire. Thus, Uncle Eustace died.

A posthumous hero, a genius accorded after a death so quizzical, so individual, yet so much of the pattern he had set himself to follow: my thoughts, my words still after thirty years confused, ceaseless in motion change from day to day and still I cannot say why this should be or if a yet more glorious world might shine had Uncle Eustace lived, lined up with others of his tribe, with Moseley and Wilfrid Owen, Rupert Brooke, the roll is endless.

I can record twenty-five monographs  
in Transactions of Academies world-wide,  
his name on plaques, on chapel walls,  
columns and references in text books, scores  
of new compounds indexed, in this  
his family name. Even the Fifth Form schoolboy fails  
if he forgets what Eustace stands for,  
and, as for his patents, Dad was very soon  
besieged by major companies in Widnes,  
Delaware, Paris, Turin and Hamburg outbidding  
all to purchase royalties for synthesis  
of basic chemicals for fertilisers, textiles,  
dyestuffs, drugs. So Father waxed, became  
commander on a field he was well qualified  
to master, transferred his offices to London,  
was made director of ten companies, Lord Mayor  
and baronet.

Succeeding him, I feel  
a conflict of emotions; undeserving, why  
should I and all my family be circled round  
with so much satiety, delight, so many friends  
and joys of love and freedom, beauty, esteem and honour  
and all because of one young uncle who  
pursued his goals with such humility  
and silence and a quiet smile? And yet  
I never can forget that glow, that steady  
luminescence in his eye which I, as child  
divined and marvelled at, sitting without movement  
beside him on the window seat, those birds,  
those flowers, as are the stars unquenchable,  
eternal, so can I never understand  
how light of such a clarity can fade,  
what medium that I can comprehend  
could generate the power  
to drown and snuff it out?

Deric Bolton\*

*Deric Bolton was, until 1971, a chemist with Macfarlan Smith Ltd, Edinburgh. His four published collections of poetry include The Wild Uncharted Country (1973), a narrative sequence on life in the chemical industry.*

## Three centuries of alcohol in the British diet

Josephine A. Spring & David H. Buss

Nutrition Section, Ministry of Agriculture, Fisheries and Food, London, UK

*Alcoholic drinks were consumed in larger quantities in the eighteenth and nineteenth centuries than in the twentieth century, although there has been a recent increase from the historical low of 1930–60. Beer, spirits and wines once provided at least 2 MJ (nearly 500 kcal) per person per day compared with 0.67 MJ (160 kcal) in 1975, towards an average energy requirement of the total population little different from that needed now. Beer has always contributed most to the alcohol, energy and nutrient content of the diet, although its importance relative to spirits and wine has declined.*

THERE is much concern about the amounts of alcohol drunk in the United Kingdom<sup>1,2</sup>. It is believed that men and more particularly women and children are drinking more, resulting in increased prevalence of drunkenness<sup>3</sup>, driving under the influence of alcohol<sup>1,3</sup>, alcoholism<sup>4</sup>, liver cirrhosis<sup>4</sup>, and absence from work owing to excessive intake of alcohol<sup>5</sup>. It is, however, very difficult to obtain accurate information from individuals. Most, when asked, are likely to underestimate their consumption, while some, wishing to impress the interviewer, exaggerate their capacities.

A more objective assessment of overall trends can be obtained from HM Customs and Excise Department, which records, for tax purposes, the total amounts of beer, spirits and wines retained for consumption within the United Kingdom (except for the small amounts of beer and wine made in the home). Since 1955 the Ministry of Agriculture, Fisheries and Food has assessed the energy content of these drinks and compared them with the energy content of the national food supply<sup>6</sup>. The results are summarised in Table 1.

We wished to place these figures into historical perspective, for this rise in the consumption of alcoholic beverages started

from an historical low point. Customs and Excise records, with brief exceptions, have been collected since 1684 and are summarised in Fig. 1. Note that this figure is an average for the total population of the country, including young children who nowadays consume little or no alcohol. A discussion of separate trends for each beverage will be followed by a general discussion of the major factors which can affect consumption. Tables 2 and 3 list some of these.

### Beer

Ale has been drunk in England since Celtic times<sup>7</sup> and hopped beer since the fifteenth century, but it was not until 1643 that a beer duty was imposed to raise money for the Civil War. The earliest national records of consumption date from 1684, when the beerhouse was the centre of the working man's life. Many workers were paid at public houses, which also served as labour exchanges; if a man was unemployed he could receive credit if he was a regular customer<sup>8</sup>. Inns also served as centres of transport, courts and even small prisons, such as the White Lion at Southwark<sup>9</sup>. Entertainments such as cock fighting, bear baiting and prize fighting also took place in them. In the late seventeenth and early eighteenth centuries it was wiser to drink beer than the usually polluted drinking water. For example, Nottingham's water supply was drawn from the River Leen which also served as the main sewer of the town; fortunately Nottingham had one alehouse for every 80 inhabitants<sup>9</sup>.

Beer consumption reached a maximum of 832 pints per person per yr (or 2.3 pints per person per d) in 1689. Consumption dropped sharply when the duty was tripled (see Table 2) with partial recoveries after 1700 and 1712 when part of the tax was transferred to the constituent malt. Consumption then declined steadily until 1790 while the duty remained relatively static (as did the price: in London porter remained at 3 pence per quart until 1761 and 3½ pence until 1799 when it was increased to 4 pence<sup>9</sup>). There are no obvious reasons why consumption

**Fig. 1** Beer, spirits and wine available per person in the United Kingdom. *a*, Production figures for beer represent barrellage brewed by common brewers and brewing victuallers, corrected until 1830 to include private brewing. From 1684 to 1830 they are taken from Monckton<sup>23</sup>, from 1831 to 1936 from Wilson<sup>11</sup> (appendix F) and from 1937 to 1975 from the Annual Reports of HM Customs and Excise Department<sup>24</sup>. Volumes and populations refer to England, Scotland, Wales and Ireland up to 1922; afterwards Eire has been excluded. *b*, Values for spirits from 1684 to 1799 are from the Department of Inland Revenue<sup>24</sup>, from 1800 to 1935 from Wilson<sup>11</sup> and from 1936 to 1975 from the Brewers Statistical Handbook<sup>3</sup>. Volumes and populations refer to England only until 1713, and between 1718 and 1724 to England and Ireland. Thereafter they are for the United Kingdom. *c*, Values for wines from 1697 to 1900 are taken from Wilson<sup>11</sup> and from 1901 to 1975 from HM Customs and Excise<sup>24</sup>. Until 1787 they refer to wines imported into England, but subsequently are the amounts retained for home consumption in the whole United Kingdom (including Eire until 1922). The populations of the appropriate regions of the United Kingdom for decennial periods from 1684 to 1831 are from the Department of Inland Revenue<sup>25</sup> and thereafter from the Registrars General<sup>14</sup>.

decreased during this period, although from 1750 the enclosure of agricultural land and the initiation of the industrial revolution (which shifted population to the manufacturing towns) must have reduced home brewing<sup>10</sup> particularly in the North and Midlands. In the South shortages of fuel had a similar effect<sup>7</sup>. In 1791 a tripling of the malt duty resulted in another sharp fall in consumption. Records from here until 1880 are incomplete, for almost all those provided by the Brewing Victuallers' Association between 1791 and 1818 are lost and those between 1831 and 1880 have been derived from a mathematical conversion of malt to beer<sup>11</sup>, because beer itself was not taxed during this period, only malt and hops, and, from 1847, sugar. Consumption apparently increased as a result of the Beer House Act 1830 which allowed anyone who bought a 2-guinea licence to sell beer; 40,000 new public houses were opened within 5 yr (ref. 11).

In 1880 Gladstone introduced his free mash tun system allowing brewers to use carbohydrate sources other than malt, the duty being charged on the original gravity of the beer. This led to a decrease in price which, coupled with the nation's prosperity, caused consumption to rise to nearly 1 pint per person per d in the latter part of the nineteenth century. Thereafter consumption fell again, accelerated by an increase in duty in 1900, and reached its lowest recorded level in 1918. During World War I opening hours were restricted (see Table 3), and in 1917 production was reduced from 26 million to 10 million standard barrels and the gravity of the beer greatly reduced. The weakness and expense (after several increases in duty) resulted in a boycott of beer in many places. After the war consumption recovered, but then fell with the economic depression of the 1930s. World War II prompted a substantial increase in consumption, mainly because of the unavailability of spirits and wines, but demand was met by a reduction in gravity. Despite increases in duty, consumption remained stable after the war and rose from the late 1950s. Nevertheless the amount of beer available in the 1970s is considerably lower than it was 100 years ago.

A recent estimate put the amount of home-brewed beer produced from kits at 1.75 pints per person per yr.

Tax has been levied on cider for a few short periods only, and consumption is thus known for relatively few years. From 1756 to 1765 it ranged between 2.5 and 5 pints per person per yr; in 1820 and 1830 it was 2 pints but declined to little over 0.5 pints in some of the intervening years; and it enjoyed a brief increase to 4 pints at the end of World War I. The Cider Manufacturers Association have calculated cider consumption since 1946 as about 3 pints per person per yr until 1965, after which it rose rapidly to 5.8 pints in 1975<sup>3</sup>. Cider has been taxed since that year.

## Spirits

Before the Restoration the consumption of spirits was small, but after 1660 consumption, mainly of brandy, increased<sup>7</sup>. In 1688 William of Orange became king and encouraged the production of gin by issuing charters to divert the surplus English grain for its production; in 1690 imports of foreign spirits were prohibited. In Queen Anne's reign the monopoly privileges of the Worshipful Company of Distillers were cancelled; this led to the unlimited production of gin, much of poor quality, which was sold in the streets and hawked from door to door at 1 penny per pint. The steady increase in consumption was checked in 1729 by the introduction of retailer's licences costing £20 per yr and the prohibition of street hawking. Distillers retaliated with a flavourless, low quality spirit, not classed as gin (known as Parliamentary brandy). In 1733 the Act was repealed, and another introduced which limited the sale of spirits outside dwelling houses. This led to the development of the 'gin shops' typified in Hogarth's engraving 'Gin Lane'<sup>12</sup>. Thus gin and other crude spirits were both cheap and readily available at a

**Table 1** Increasing contribution of alcoholic drinks to the diet

Year	Energy from food MJ (kcal)	Beer (pints)	Spirits (proof pints)	Wine (pints)	Energy from alcoholic drinks (% of food energy)
1955	13.3 (3,170)	140.2	1.8	2.7	3.0
1958	13.3 (3,180)	138.2	2.0	3.2	3.0
1961	13.2 (3,150)	155.8	2.4	4.3	3.5
1964	13.2 (3,160)	160.3	2.7	5.5	3.7
1967	12.9 (3,080)	165.6	2.6	6.1	3.9
1970	13.0 (3,110)	178.6	2.8	6.6	4.1
1973	12.2 (3,040)	196.9	4.3	11.2	5.0
1976	12.3 (2,930)	209.0	5.1	12.0	5.7

The energy content of the food supplies relates to the total quantities available in the UK from agriculture and imports, less exports and non-food uses, and is expressed per person per d. The quantities of each alcoholic drink (per person per yr) are derived from Customs and Excise records, and their energy content includes any carbohydrate as well as the alcohol present. 1 litre = 1.76 pints.

Table 2 Major changes in duties charged on alcoholic drinks

Beer and constituents		Spirits		Imported wines		Index of wholesale prices <sup>24-27</sup> (1860 = 100)	
1643	Small beer 6d; strong beer 2/-	1684	2d-4d	1787	French 2/3d-3/1d	1680	55
1690	Small beer 1/6d; strong beer 6/6d	1751	1/- - 1/3d		Rhenish 3/1d	1700	80
1710	Small beer 1/4d; strong beer 5/-;	1783	5/10 $\frac{1}{2}$ d		Spanish 2/-	1750	70
	malt 6 $\frac{1}{2}$ d	1785	2/7 $\frac{1}{2}$ d		Portuguese 1/6d	1800	125

1974	Beer 186/-	1976	492/-	1969	Light 32/2d; heavy 54/2d		
1975	Beer 273/-			1973	Light 17/7d; heavy 39/6d		
1976	Beer 317/-			1975	Light 53/6d; heavy 70/-		

12d (pence) = 1/- (shilling) = 5p (new pence). Beer duty is per barrel (163.6 l), malt and hops per bushel (36.4 l) and sugar per hundred-weight (50.8 kg). Spirits duty is per proof gallon, that is per gallon (4.5 l) with strength corrected to 100° proof or 49.276% alcohol by weight. Wine duty is per gallon.

time when the social conditions of the urban poor were extremely bad with little hope of escape other than intoxication<sup>13</sup>.

The Acts of 1751 and 1752 (Table 3) resulted in a dramatic decline in consumption and for the rest of the century consumption largely reflected impositions of duty.

The wild fluctuations of the next 20 yr may be partly due to a breakdown in the system by which spirits were taxed. Indeed it was not until 1824 that the figures of the Excise Department approximate to the real production<sup>14</sup>, and all estimates of production before this date must be regarded as conservative because of the amount of illicit distilling which was practised, particularly in Ireland and Scotland. Thereafter consumption was again influenced by duty and legislation, and religious opinion had further effects: for example Father Matthew's temperance mission in Ireland caused consumption there to drop by 23% between 1839 and 1845<sup>11</sup>. By the early 1870s, however, the equivalent of 4 ounces of proof spirit was consumed per week for every man, woman and child in the country; this was a time of great prosperity in the United Kingdom. Thereafter duty increases and trade depressions led to a steady decline.

In World War I, opening hours were curtailed, and the manufacture of spirits was then reduced on the orders of the food controller in 1917 to half that produced in 1916<sup>11</sup>. In 1918 consumption rose dramatically with the post-war celebrations in spite of increased duties, but then declined right through the economic depression and on into World War II when available grain was used for food rather than distillation. Consumption recovered after World War II despite increases in duty in 1947, until in 1964 a substantial increase in duty led to a stable consumption rate. In 1973 the duty was decreased and the increase in consumption has now continued in spite of several more tax increases.

## Wines

In the Middle Ages wine drinking was common in Britain and consumption was relatively high. The dissolution of the monasteries led to the disappearance of the British vineyards<sup>7</sup>. As a result, the pattern of consumption has since been largely determined by treaties, wars and tariff levels.

In 1703 the Methuen Treaty between England and Portugal allowed the import of Portuguese wine at a fixed and relatively low duty, in return for concessions on the exports of woollen cloth to Portugal<sup>11</sup>. This treaty remained in force until 1831 and

was the principal reason why the British drank port during the eighteenth century rather than claret as before. Between 1704 and 1785 the proportions of wine, by country of origin, which were consumed in Britain were Portuguese 65.4%, Spanish 29.3% and French 3.6%<sup>11</sup>. Consumption of port and other fortified wines was largely confined to the richer members of the community: for example one Dr John Campbell drank 13 bottles at one sitting and many men habitually drank 4 bottles of port a day<sup>13</sup>.

In 1783 a new treaty with France lowered the duties on French wine. This was partly designed to combat the smuggling of French wines, which was rife, and it led to an increase in consumption in the 1780s. This continued into the next century despite the Napoleonic wars and was followed by a decline in consumption in the post-war depression until 1825 when the wine duties were altered<sup>11</sup>. Consumption remained steady until 1860 when the Cobden Treaty was signed with France, and the wine duty was reduced. This was followed in 1861 by the duties charged being based on the alcoholic strength of the wine; a lower rate was levied on 'light' wines not exceeding 20° proof

Table 3 Major statutes affecting consumption

Date	Statute	Effect
1751	An Act . . . for more effectually restraining the retailing of distilled spirituous liquors	Greatly increased duty on spirits
1752	The Disorderly Houses Act	Controlled excessive numbers of public houses
1828	The Alehouses Act	Restricted opening hours
1830	The Beerhouse Act	Allowed beer sales on licensed premises only
1848	The Alehouses and Beer-houses Act	Restricted opening hours
1854	The Sunday Beer Act	Reduced opening hours on Sundays
1872	The Licensing Act	Restricted numbers of licences
1908	Children's Act	Children under 14 not allowed to enter bars
1914	The Defence of the Realm Act	Public houses closed at 11 p.m. weekdays, 10.30 p.m. Sundays
1923	An Act (on) the sale of intoxicating liquor to persons between 14 and 18 years of age	Illegal to sell intoxicating liquor to anyone under 18
1945	The Licensing Planning Act	Controlled redevelopment of public houses in bombed areas

spirit. Consumption increased during the mid-Victorian period of prosperity, but declined after 1875 because of an economic depression. Consumption of port increased despite the higher rates of duty on fortified wines, but later declined perhaps because after-dinner smoking became fashionable instead. Sherry consumption increased until 1873, when the demand was so great that poor quality wine was sold to meet this demand and led to consumer resistance<sup>11</sup>.

Apart from a small peak at 1900, consumption continued to decline up to and during World War I. During the war years wine consumption was not affected as much as beer or spirits: although imports of wine were checked and formal entertaining was curtailed, consumption was stimulated by the low-gravity beer and shortage of spirits<sup>11</sup>. Post-war celebrations doubled the consumption in 1919, but this was reversed by an increase in duty in 1920. Consumption recovered a little in the 1930s but almost no wine was available during World War II because of the shipping blockade and the fact that many of the wine-producing countries were controlled by Axis powers.

Consumption rapidly recovered after the War, encouraged by a variety of stimuli. A reduction of duty in 1973 caused a further steep increase in consumption; the increases in duty in 1976 and 1977 seem to have checked this.

### British wines and mead

Little is known about consumption of British wines before 1927 because this wine was taxed only for a few short periods. Consumption rose from 0.5 pints in 1930 to nearly 1.2 pints per person per yr in 1939, only to fall to 0.5 pints again during World War II. Only in 1960 were pre-war levels reached again. This upward trend has continued and reached 2 pints in 1975. A recent estimate shows that home wine making from kits provides 0.33 extra pints per person per yr.

### Factors affecting consumption

The consumption of alcohol depends on four factors: price, availability, current social pressures, and educational or moral campaigns<sup>11</sup>. Economic factors seem to be of paramount importance, as the fluctuations in the consumption of alcohol closely follow the rise and fall in the general trade of the country. Years of prosperity such as 1875 and 1899 were years of much drunkenness<sup>11</sup>, and this is illustrated by Booth's evidence from a London policeman during the 1880's: "a great amount of drunkenness is still a sure sign of work being plentiful. It is then that the police are busiest"<sup>15</sup>. Equally the economic depressions of 1855–60, 1875–80, 1894, 1904, 1909 and 1928–35 were years of modest consumption. Furthermore, as we have seen, consumption is sensitive to purchase price. The prices of beer, spirits and wines relative to each other, and relative to other beverages and to food and other goods in general, also affect consumption. Coffee was introduced to England in 1637 and tea and cocoa followed around 1650<sup>7</sup>. They were luxuries at first and drunk only by the wealthy, but by 1800 the price had fallen far enough to make their use universal. Tea consumption rose from 1.4 pounds per person per yr in the first decade of the nineteenth century to 5.7 pounds in the last decade (and is now 7.7 pounds). Similarly coffee consumption increased from 1.1 ounces per person per yr in 1801 to 16 ounces in 1880, but then declined. (It has recently reached about 80 ounces.) Cocoa imports grew from 0.5 ounce per person in 1822 to 10.4 ounces per person in 1894. And between 1841 and 1882 taxes on tea, sugar, coffee and corn were lowered from £15.8 million to £4.8 million, while those on beer, spirits, wine and tobacco rose from £18.1 million to £37.3 million<sup>16</sup>; this helped tea to displace beer as the main drink of the poor. The price of alcoholic beverages relative to other food has also decreased recently, and it has been estimated that the number of minutes work required from a male manual worker to pay for a large loaf (1½ pounds), 1 pint of beer and a bottle of whisky have changed from 9, 23 and 659 respectively in 1950 to 11, 12 and 209 in 1976<sup>17</sup>.

**Table 4** Decreasing contribution of alcoholic drinks to nutrient intakes (mg per person per d)

	Iron	Calcium	Magnesium	Riboflavin	Nicotinic acid
1691	0.27	150	133	0.83	15.7
1741	0.20	110	97	0.61	11.5
1791	0.14	67	59	0.37	7.0
1841	0.09	47	41	0.26	4.9
1891	0.12	60	54	0.38	6.3
1941	0.05	27	24	0.15	2.8
1971	0.10	29	25	0.10	1.5
Recommended intake*	10.0	500	300	1.7	18.0

Iron was calculated for both wines and beer, and the remaining nutrients for beer alone as any contribution from wines or spirits was insignificant. For derivation of nutrient content of earlier liquors, see text.

\*Recommended intake for a moderately active male aged 18–35yr<sup>19</sup>. The recommendation for magnesium comes from the Canadian recommended daily intakes<sup>28</sup>.

Licensing hours control consumption of all drinks on licensed premises, though any person aged 18 or over may purchase as much alcohol as he wishes to consume at home.

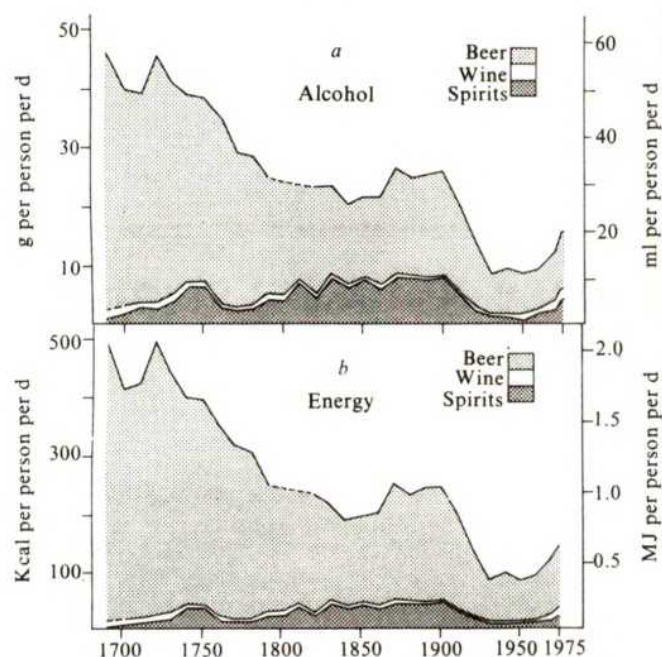

Social factors which affect consumption are of two types. Those which tend to decrease consumption include the social unacceptability of being drunk, the laws regarding drinking and driving and counter-attractions such as the availability of non-alcoholic refreshments, the acquisition of cheap consumer goods, smoking, gambling, thrift, travel, the cinema, radio and television which competed with alcohol for an individual's spending money. On the other side of the coin concern has been expressed about social conventions which lead to higher consumption in certain occupations such as business executives<sup>5</sup>; this is, however, a convention of long standing as Booth remarks on its prevalence in the 1880s<sup>15</sup>. Publicity has also been given to the so-called 'lace-curtain drinking syndrome' among those married women who can afford it; this too is not a new problem as Booth relates "All round London are growing up suburbs of small houses whose occupants have just enough to live on comfortably. Women are left at home, small ailments, the immediate stimulus of drink, that is how it begins"<sup>15</sup>. Booth also related the increase in alcohol consumption in women in the 1880s to their emancipation and increasing financial independence from men. In recent years the sale of alcohol in supermarkets, and liquor trade advertisements equating alcohol with glamorous living, may have tended to increase consumption.

The temperance movement has been the most prominent moral and educational force to affect consumption. The Victorian middle classes were horrified by drunkenness and especially by its increase amongst the working classes as they became more prosperous. Although their ancestors had accepted excessive consumption without question, they began to denounce it as an unmitigated evil. Previous social reformers had denounced spirits but had recognised beer as a cheap and wholesome drink greatly preferable to impure water, but from the 1850s temperance reformers zealously condemned all alcoholic beverages and achieved much in the imposition of restrictions on the sale of drink to children (see Table 3). The temperance movement was a formidable demonstration of the power of organised middle-class opinion and of the 'non-conformist conscience'<sup>18</sup>.

### Contributions to diet

The relative contributions made by beer, spirits and wines to the diet are disguised when each is recorded in terms of volume. Spirits have a very high energy content and 1 proof pint (equivalent to about 1.42 pints at 70° proof) provides about 7.5 MJ or 1,800 kcal, but essentially no other nutrient. Wines contain much less alcohol, even when fortified, and despite their

**Fig. 2** Relative contributions of beer, spirits and wine to the diet; *a*, in terms of alcohol and *b*, in terms of energy. Values for 1821, 1831, 1951, 1961, 1971 and 1975 include the contributions made by cider and British wines. The alcohol and sugar contents of beer at original gravity 1,055° were each taken as 4.2 g per 100 ml (ref. 10); the alcohol content of spirits is fixed when quantities are recorded in proof gallons; and wines were calculated on the assumption that French, Rhenish and Empire or Commonwealth wines were 'light' and could be treated as an equal mixture of red, rose and white wines, while wines from Portugal, Spain and their colonies were 'heavy' and could be treated as an equal mixture of port, sherries and vermouth. The alcohol and energy values of these and cider were then derived from standard tables of food composition<sup>20</sup>. Any errors in the assumptions necessary for wines are trivial while consumption has been so low.

sugar content they also provide less energy. The small amounts of iron and other nutrients are of little significance when the low consumption is averaged over the whole population. Beer contains the least alcohol, but in the amounts drunk its contribution to the energy (with 1 pint as drunk now providing between 0.6 and 1.7 MJ) and B-vitamin content of the diet can be substantial.

Figure 2 shows the amounts of alcohol and of energy provided by beer, wines and spirits. Although they are expressed per head of the population, each has been restricted to certain sections of the population, each of which would have drunk much more than the averages illustrated. Even so, it is obvious that the total amount of alcohol available has declined fairly steadily. Beer has always provided the most alcohol although the percentage has in general declined and now stands at 67%. Spirits have never provided more than a third of the total alcohol available; they now provide about 20%. Wine has recently become relatively more important.

The energy provided has changed almost exactly in parallel with the alcohol content (Fig. 2). The main difference is that spirits, which contain little or no carbohydrate, make a relatively smaller contribution to energy than to alcohol. The three beverages together provided between 1.5 and 2.5 MJ (400–500 kcal) per person per d in the first half of the eighteenth century, but this had fallen to less than 1 MJ (200 kcal) 100 yr later. After a rise to just over 1 MJ (250 kcal) in the latter part of the nineteenth century, it remained at an historical low of about 0.4 MJ (100 kcal) from 1930 to 1960 but has now increased again to about 0.6 MJ (150 kcal) per person per d.

Beer is and always has been the greatest source of energy as alcohol (on average) although its contribution has fallen from 92% of the total from all alcoholic drinks in 1731 to 77% in

1831, and from 84% in 1931 to 79% in 1971. Spirits have provided up to one-fifth of the total, while the contribution from wine, although small, has increased from 5% in 1731 (when most of the wine was fortified) to 9% in 1971 despite the relatively recent increase in the proportion of light wines with only two-thirds the energy value of their fortified counterparts.

It is not possible to calculate the relative importance of food and alcohol to the diet for most of the period covered, because few national surveys of the total food supply were attempted before 1940. We have, however, estimated the average energy requirement of the population at selected times, to determine what proportion of this was likely to have been satisfied by alcoholic drinks. The different age and sex structures of the population (particularly the greater proportion of children in earlier years) were taken into account from Census data, and present recommendations<sup>19</sup> for each group were then applied to these on the assumption that in the nineteenth century all men and women were 'very active' and in the twentieth century they were 'moderately active'. The average requirement of the population was then approximately 10.3 MJ (2,460 kcal) per person per d in 1821, 10.5 MJ (2,500 kcal) in 1871 and 10.8 MJ (2,570 kcal) in 1911 compared with about 9.8 MJ (2,350 kcal) in 1971; the proportions met by the alcoholic drinks available thus averaged 10% in 1821 and 1871 and 8% in 1911, compared with about 5% in 1971.

Table 4 shows the amounts of three minerals (iron, calcium and magnesium) and two B vitamins (riboflavin and nicotinic acid) estimated to have been provided by the beer available in selected earlier years. The minor contributions of the different wines to iron intakes are also included, but the amounts of other nutrients provided by alcoholic drinks were insignificant.

Values for 1971 were derived from standard tables of food composition<sup>20</sup>. Earlier values are the best estimates we can make in the virtual absence of direct information, and were obtained as follows. The B vitamins in beer, being derived mainly from the malt, seem to be related to the strength of the brew; thus, a sample of strong ale supplied to Queen's College, Oxford before World War II contained 0.39 mg riboflavin per 100 ml (ref. 2) compared with 0.06 mg in strong ale and 0.04 mg in draught bitter brewed recently<sup>20</sup>. Other analyses of beer in the 1930s and 1940s showed more riboflavin and nicotinic acid than in modern beers—0.08 mg per 100 ml (including one bottle brewed in 1798)<sup>21</sup> and 1.5 mg per 100 ml (ref. 22) respectively. These values were used in assessing intakes for 1941 and earlier. The vitamin and mineral contents of beers in previous centuries have thus been related to their original gravity.

Given these assumptions beer (and wine) seems to have made a major contribution to the nutritional value of diets in the seventeenth and eighteenth centuries, and especially to riboflavin, nicotinic acid, calcium and magnesium intakes.

We thank the librarians of the Customs and Excise Department for their help in making so many old records available, and the Trade Associations and many brewers and other individuals who provided information and advice.

# Interparticle forces in multiphase colloid systems: the resurrection of coagulated *sauce béarnaise*

C. M. Perram\*, C. Nicolau† & J. W. Perram‡

Châlet Friedheim, 6386 Wolfenschiessen, Nidwalden, Switzerland

*The successful preparation of sauce béarnaise is reported. The physico-chemical factors influencing the stability of this colloidal system are considered.*

VARIOUS authors have extensively described<sup>1–5</sup> the preparation of *sauce béarnaise* (SB), the colloquial name for a (hopefully) stable colloidal suspension consisting of a hydrophobic phase suspended in a low pH aqueous phase at different ionic strengths. It is highly probable that the colloidal particles are micelles consisting of a mixture of phospholipids, fats, proteins, cholesterol and various long-chain unsaturated fatty acids. The aqueous phase contains mainly acetic acid and sodium chloride at ionic strengths determined by the initial conditions. Chlorophyll-containing additives, we believe, have little influence on the colloidal properties of the system.

We shall first give a brief description of the underlying physico-chemical principles. Hydrophobic colloidal suspensions exist because of an interplay of double-layer repulsion and attractive dispersion forces. The latter are relatively independent of the composition of the dispersive medium and temperature although in some circumstances this assumption cannot be justified<sup>6–9</sup>. The double-layer repulsions arise from the surface charge resulting from ionisation of adsorbed acetic acid, in this case, screened by the dispersing electrolyte solution<sup>10</sup>. This contribution to the forces can clearly be influenced by the conditions prevailing in the dispersive medium. The aim of this article is to indicate how an understanding of this interplay of forces can lead to more complete experimental control of the stability of this extremely complex and important system.

## Theory

Although we can find no definitive light or neutron scattering data on this system, we assume that the micelles are spherical, and hence that the Van der Waals forces between them are well described by the equation of Hamaker<sup>11</sup>

$$U_A = -\frac{A}{6} \left[ \frac{2}{a^2 - 4} + \frac{2}{a^2} + \ln \frac{a^2 - 4}{a^2} \right] \quad (1)$$

where  $U$  is the interaction energy relative to infinite separation,  $a$  is the non-dimensional interparticle separation scaled with respect to the particle radius and  $A$  is the so-called Hamaker constant, with a value of about  $10^{-12}$  erg. The number of adsorbed acetic acid molecules per unit area of the particles may be predicted from the ambient bulk concentration and a suitable adsorption isotherm<sup>12,13</sup>. The fraction of these which are dissociated will naturally depend on the composition of the dispersive medium,

particularly the pH. Furthermore, we can expect that the solvation by acetic acid of the ionic groups on the colloid particles will significantly affect the stability of the particles<sup>14</sup>. If there are  $N_s$  dissociated acid groups per unit area these contribute a surface charge

$$\sigma_N = N_s q \quad (2)$$

where  $q$  is the protonic charge. The ionic strength

$$\mu = \frac{1}{2} \sum_{i=1}^N \rho_i z_i^2 \quad (3)$$

of the dispersing medium will result in a screening of the coulombic repulsion due to the negative charges on the particles' surfaces. The potential of these forces decays with distance  $r$  according to an exponential law<sup>6</sup>:

$$F \sim \psi_0^2 [1 - \tan h \kappa L/2]$$

where:  $\psi_0$  = surface potential,  $\kappa$  = inverse Debye length, and

Fig. 1 Potential curves for the interparticle interaction in a multiphase colloid system.

8*	3	3	—	—
9*	3	3	—	—

\*The authors.

 $L$  = distance between the particle surfaces.

The various contributions and overall potential energy curve are shown in Fig. 1. If the height of the maximum in the potential curve is large compared to  $kT$ , where  $k$  is Boltzmann's constant and  $T$  the absolute temperature, then the sauce (SB) will be stable.

This maximum will be increased by the surface charge and reduced by increasing either temperature or ionic strength. This accounts for the empirical observation that the application of multivalent ions has never been recommended in the manufacture of *sauce béarnaise*. Only the increase of  $\sigma$  can have a beneficial influence on the stability of the product.

### Experimental methods

Commercially available reagents (vinegar, onion, egg yolks, butter, parsley, tarragon, *herbes de Provence*, mustard, pepper, NaCl and alpine water ( $H_2O$ )) were used, according to ref. 3. We do not expect that our conclusions would have been altered if the alternative procedures<sup>1,2,4,5</sup> had been used. In our hands, heavy

coagulation was observed despite vigorous stirring and careful temperature control ( $\pm 5$  K). When coagulation occurs, other authors recommended discontinuation of the experiment<sup>1-5</sup>. However, based on the above theoretical considerations, we decided to add, with extremely vigorous stirring, a further quantity of the commercially available acetic acid solution, and the results confirmed our theoretical predictions.

### Results and discussion

After addition of acetic acid, and as vigorous stirring proceeded, the heterogeneous phase soon assumed the expected homogeneous consistency. Examination of the resulting preparation was immediately undertaken by a significant number of trained observers. The results of this examination are listed in Table 1. To our knowledge, this is the first successful attempt to resurrect a *sauce béarnaise* based on the theory of the stability of lyophobic colloid<sup>10</sup>.

Thanks are due to Drs K. Hildenbrand, A. Reimann and to M. Hildenbrand, V. Hallmann, H. Dittich and I. Hengst for agreeing to take part in the experiment.

*Indicators of large-scale climate developments show that the oscillatory cooling observed in the past 30 yr in the Northern Hemisphere has not yet reversed. This conclusion was reached by updating our data on the month-to-month, season-to-season, and year-to-year variations of selected zonally averaged meteorological parameters.*
